Extremely low detection limits (below  $\mu\text{g l}^{-1}$ ) are achieved due to the preconcentration step. Additionally, the method allows multielement detection and the apparatus required for the analysis can be purchased for a relatively small cost.

### Principles

#### The Preconcentration Step

By far the most common mode of preconcentration is the accumulation of a metal ion by the formation of an amalgam in a mercury drop or thin mercury film by electrolytic reduction at a fixed potential:

Amalgam-forming elements such as cadmium, copper, lead, zinc can be determined simultaneously in this way. Other elements such as arsenic, mercury, and silver can be determined by electrolytic reduction

**Figure 1** Typical stripping chronopotentiogram obtained from PSA. After an initial accumulation period,  $t_{\text{acc}}$ , at potential,  $E_{\text{acc}}$ , potentiostatic control of the electrochemical cell is discontinued and change in potential is plotted versus time.

## POTENTIOMETRIC STRIPPING ANALYSIS

**M Honeychurch**, University of Queensland, Brisbane, QLD, Australia

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Potentiometric stripping analysis (PSA) has become more widely used over the last 20 years in part because of the advent of commercial instrumentation during that period. In many ways the method is analogous to voltammetric stripping methods insofar as it comprises an initial preconcentration step in which the analyte is accumulated onto or into the working electrode followed by a stripping step in which the analyte is 'stripped' back into solution. The electrochemical cell is under potentiostatic control during the accumulation period,  $t_{\text{acc}}$ ; however, during the stripping step the potentiostatic control is discontinued and the change in the working electrode potential versus time is measured. Therefore, the method is more appropriately termed chronopotentiometric stripping analysis. The output is a sigmoidal-shaped chronopotentiogram (**Figure 1**) with each plateau (parallel to the potential axis) corresponding to the transition or stripping time,  $\tau$ . This is analogous to a potentiometric titration with each plateau corresponding to an 'endpoint' equating to the complete reaction of the accumulated analyte with the difference being that the change in electrode potential is plotted versus time rather than versus the volume of titrant added.

Extremely low detection limits (below  $\mu\text{g l}^{-1}$ ) are achieved due to the preconcentration step. Additionally, the method allows multielement detection and the apparatus required for the analysis can be purchased for a relatively small cost.

### Principles

#### The Preconcentration Step

By far the most common mode of preconcentration is the accumulation of a metal ion by the formation of an amalgam in a mercury drop or thin mercury film by electrolytic reduction at a fixed potential:

Amalgam-forming elements such as cadmium, copper, lead, zinc can be determined simultaneously in this way. Other elements such as arsenic, mercury, and silver can be determined by electrolytic reduction

**Figure 1** Typical stripping chronopotentiogram obtained from PSA. After an initial accumulation period,  $t_{\text{acc}}$ , at potential,  $E_{\text{acc}}$ , potentiostatic control of the electrochemical cell is discontinued and change in potential is plotted versus time.

at solid electrodes such as gold or bismuth. An alternative method of electrolytic preconcentration occurs by electrolytic oxidation during which the mercury working electrode is oxidized and an insoluble salt is formed between the electrode and (generally) inorganic anionic analytes:

During the preconcentration step, only a small amount of analyte is being removed from the solution; therefore, the bulk concentration of the analyte in solution is assumed to be constant. It is also assumed that the kinetics of amalgamation is sufficiently rapid for the process to be mass transport controlled. The amount of the analyte that is accumulated during the preconcentration step is proportional to the bulk concentration. For example, the concentration of an amalgamated metal ion is

$$[\text{M}(\text{Hg})] \propto \frac{D_{\text{M}^{n+}} [\text{M}^{n+}] t_{\text{acc}} A}{\delta_{\text{acc}}} \quad [3]$$

where  $D_{\text{M}^{n+}}$  is the diffusion coefficient,  $A$  the electrode area,  $t_{\text{acc}}$  the accumulation time, and  $\delta_{\text{acc}}$  the diffusion layer thickness during the accumulation process. Increasing the  $t_{\text{acc}}$  increases the amount of analyte accumulated, thereby increasing the analytical signal and lowering the detection limit (Figure 2). Some trade-off is inevitably made between electrolysis

time and detection limit. Stirring the solution during the preconcentration reduces the diffusion layer thickness  $\delta_{\text{acc}}$ , thereby increasing the amount of analyte that is accumulated and reducing the accumulation period that is required.

Since the early 1980s, a number of methods have been developed to analyze various compounds by stripping voltammetry following the adsorptive accumulation of the species on the electrode. The adsorptive accumulation procedure has enabled analysts to measure extremely low concentrations of species that cannot be accumulated by amalgam formation. Species measured following adsorptive accumulation include metal complexes, organic compounds, and many biological macromolecules:

Adsorptive accumulation can also be used in chronopotentiometric stripping as the preconcentration step allowing a large number of organic compounds to be determined. It is assumed that the adsorption kinetics is sufficiently rapid for the process to be mass transport controlled. During the preconcentration step, the solution is normally stirred in order to enhance the mass transport of the analyte to the electrode surface, thereby reducing the time required for preconcentration. For nonelectrolytic or adsorptive accumulation,  $t_{\text{acc}}$  has an upper limit governed by the time required for the electrode to be saturated with a monolayer of adsorbate. This is determined experimentally and will depend on the mass transport conditions that exist in the electrochemical cell. For example, the amount of adsorbed metal ion complex would be

$$\Gamma_{\text{ML}_m^{n+}} \propto \frac{D_{\text{ML}_m^{n+}} [(\text{ML}_m)^{n+}] t_{\text{acc}} A}{\delta_{\text{acc}}} \quad [5]$$

where  $\Gamma_{\text{ML}_m^{n+}}$  is the surface excess of  $(\text{ML}_m)^{n+}$ , for  $t_{\text{acc}} \leq t_{\text{mon}}$ , with  $t_{\text{mon}}$  being the time required to form a monolayer and constant after that.

### The Stripping Step

In stripping voltammetry, the stripping step comprises the application of a potential sweep and the measurement of current versus potential. In chronopotentiometric stripping, the analyte is stripped by the application of a constant oxidative or reductive flux while the change in the potential of the working electrode versus time is measured. This is normally performed in an unstirred solution to minimize mass transport and consequently maximize the stripping time.

In the literature, the term 'potentiometric stripping analysis' is generally reserved for cases where the

**Figure 2** Increasing the accumulation time increases the stripping time.

**Figure 3** Commercial instruments display plots of  $dt/dE$  versus  $E$ , which are similar in appearance to stripping voltammograms. The area under the peak is equal to the stripping time,  $\tau$ .

constant flux is a constant chemical flux to the electrode surface and thus was originally referred to as chemical stripping. The other form of chronopotentiometric stripping that is frequently reported in the literature is referred to as constant current stripping to indicate that the constant flux is a flux of electrons.

Commercial instruments generally take the derivative of the chronopotentiogram and present the output of stripping measurements as a plot of the form  $dt/dE$  versus  $E$ . This is esthetically preferable since it produces peaks analogous to what one observes from stripping voltammograms (Figure 3). The area under each peak is the stripping time for that element.

## Potentiometric Stripping Analysis (Chemical Stripping)

Chemical stripping has its origins in the 1960s but was popularized by Jagner in the 1970s and 1980s. During a chemical stripping step the electrochemical cell is switched to open circuit at the completion of the accumulation period. Chemical stripping relies on a redox reaction between the analyte and another redox active compound in solution. The stripping of amalgamated metals ions, the most common application of PSA, provides a good example. Here, the stripping compound is usually Hg(II), which is added to the cell to form the thin mercury film working electrode by electrolytic reduction, although dissolved oxygen will often suffice as the stripping oxidant. The potential of the working electrode under open circuit, in this case a thin mercury film, is given by the Nernst equation:

$$E = E^{\circ} + \frac{RT}{nF} \ln \frac{[M^{n+}]}{[M(Hg)]} \quad [6]$$

where  $[M^{n+}]$  is the concentration of the analyte in solution at the electrode surface and  $M(Hg)$  is the

concentration of the amalgamated metal. Under open circuit conditions, the amalgamated metal is oxidized by the chemical reaction with Hg(II) (or  $O_2$ ):

Therefore, the ratio  $[M^{n+}]/[M(Hg)]$  changes with time under open circuit as Hg(II) diffuses to the electrode surface and reacts chemically with the amalgamated metal and consequently the electrode potential becomes increasingly positive over time. The oxidant Hg(II) will oxidize those amalgamated metal ions that have lower (more negative) reduction potentials. For multielement analysis after the first element is oxidized, the potential of the working electrode moves rapidly positive until the oxidation of the next species begins.

It follows that the potential of the working electrode will be sufficiently negative during the stripping step for the direct reduction of Hg(II) to occur at the electrode:

A corresponding oxidation reaction will also occur at the counter electrode. This reaction contributes to the background that is measured during the stripping step.

Several oxidants could be present in solution. For example, in non-deaerated solutions dissolved oxygen can act as an oxidant along with any Hg(II) that may have been added to the solution. The total number of moles of oxidant,  $Ox$ , reaching the electrode is

$$Ox_j \propto \frac{A\tau}{\delta_{strip}} \sum D_{Ox_j} [Ox_j] \quad [9]$$

where  $[Ox_j]$  is the concentration of oxidant  $j$  in solution,  $\delta_{strip}$  is the thickness of the diffusion layer formed during the stripping process, and  $\tau$  is the transition or stripping time. The measured stripping time will correspond to the time taken for the complete re-oxidation of the amalgamated metal. This is given by combining eqns [3] and [9] and rearranging:

$$\tau \propto \frac{t_{acc} \delta_{strip}}{\delta_{acc}} \frac{D_{M^{n+}} [M^{n+}]}{\sum D_{Ox_j} [Ox_j]} \quad [10]$$

Since the absolute amount of analyte accumulated during the preconcentration process is small the concentration of oxidant(s) in solution is assumed to be constant during the stripping process. The ratio  $\delta_{strip}/\delta_{acc}$ , which is assumed to be between 5 and 10 under normal experimental conditions, can be kept constant by keeping the stirring rate during each accumulation period constant between experiments.

The diffusion layer during the stripping process should be constant since this is performed in unstirred solution. Therefore, the stripping time becomes dependant on the concentration of the analyte in solution and the accumulation period:

$$\tau \propto [M^{n+}] t_{acc} \quad [11]$$

Since time is more easily measured than current PSA has advantages over stripping voltammetry; however, in practice very short stripping times are often measured requiring computerized equipment with high sampling rates. Nevertheless, it is usually possible to implement PSA with reduced cost relative to stripping voltammetry.

Since dissolved oxygen can be used as an oxidant no deaeration is generally required for PSA unless one is endeavoring to minimize the total oxidant concentration in order to lower the detection limit. Dispensing with the deaeration procedure results in a large time saving per analysis relative to stripping voltammetry. On the downside, PSA stripping times are slightly dependent on the concentration of elements that are stripped before it. Also the oxidant concentration decreases during electrolysis, making it difficult to maintain a constant oxidant concentration between experiments. This can be offset by using dissolved oxygen as an oxidant and using an open cell to maintain a saturated oxygen concentration during the stirred electrolysis procedure. Other negatives such as the formation of intermetallic compounds, the influence of the mercury film history, and the overlap of the analytical signal with the background signal are common to both PSA and stripping voltammetry.

Adsorbed molecules can be chemically stripped using both oxidants and reductants depending on the nature of the analyte in question. In most systems the analyte remains strongly adsorbed in both its oxidized and reduced forms. For example, the two-electron oxidation of an adsorbed metal complex would be given by the equation

The stripping time is normally orders of magnitude less than the accumulation time when adsorptive accumulation is employed. During the accumulation period, which is normally carried out at a constant potential, the oxidant is being reduced, thereby creating a diffusion layer  $\delta_{ox}$ . When the oxidation of the adsorbate is controlled by the rate of mass transport of the oxidant the stripping time is given by

$$\tau \propto \frac{\Gamma_{\text{ML}_m^{n+}} \delta_{ox}}{[\text{Ox}] D_{ox}} \quad [13]$$

Combining eqns [5] and [13] gives a similar expression for the stripping time to that for the stripping of amalgamated metal ions:

$$\tau \propto \frac{[(\text{ML}_m)^{n+}]}{[\text{Ox}]} \frac{D_{\text{ML}_m^{n+}} \delta_{ox}}{D_{ox} \delta_{acc}} t_{acc} A \quad [14]$$

If the experimental conditions are reproducible then this reduces to

$$\tau \propto [(\text{ML}_m)^{n+}] t_{acc} \quad [15]$$

## Constant Current Stripping

Constant current chronopotentiometric stripping of metal ions from amalgams has its origins in the 1950s with the theory for the stripping from a planar mercury electrode first described by Delahay. During a constant current stripping step, a constant current is applied to the electrochemical cell at the completion of the preconcentration step. For an electrolytic preconcentration, the constant current is intended to reverse the electrolytic reaction in an analogous way to the application of a potential sweep during the stripping step in stripping voltammetry. For example, an amalgamated metal would be stripped back into solution by applying a constant reducing current

This changes the ratio  $[\text{M}^{n+}]/[\text{M}(\text{Hg})]$  with time and consequently changes the electrode potential over time. The stripping time is

$$\tau \propto \frac{t_{acc}}{\delta_{acc}} \frac{D_{\text{M}^{n+}} [\text{M}^{n+}]}{i} \quad [17]$$

where  $i$  is the current applied to the cell. The stripping time can, therefore, be increased by reducing the magnitude of the current applied to the cell during the stripping step. The equation for the chronopotentiogram for both PSA and constant current stripping analysis (CCSA) stripping of amalgamated metals from a mercury film of thickness  $l$  is

$$E = E^0 + \frac{RT}{nF} \ln \frac{2l}{(\pi D_{\text{M}^{n+}})^{1/2}} + \frac{RT}{nF} \ln \left( \frac{t^{1/2}}{\tau - t} \right) \quad [18]$$

For CCSA of adsorbed molecules the situation is relatively straightforward. The stripping time is inversely proportional to the current applied to the cell

$$\tau \propto \frac{\Gamma_{\text{ML}_m^{n+}}}{i} \quad [19]$$

Therefore,

$$\tau \propto \frac{D_{\text{ML}_m^{n+}} [(\text{ML}_m)^{n+}] t_{acc} A}{i \delta_{acc}} \quad [20]$$

**Figure 4** Experimental derivative chronopotentiograms of the reduction of mercurous cysteine thiolate in  $0.1 \text{ mol l}^{-1}$  phosphate buffer, pH 7.4: (A) before and (B) after deaeration. The presence of dissolved oxygen, which is simultaneously being reduced at the working electrode, enhances the response. The dissolved oxygen is reduced in two steps (peaks on either side of a). The peak on the left is the reduction to hydrogen peroxide and the peak on the right is the reduction of hydrogen peroxide to water. (Reproduced with permission from Honeychurch MJ and Ridd MJ (1995) The effect of a non-adsorbing electroactive species on the transition time in derivative adsorptive chronopotentiometric stripping analysis. *Electroanalysis* 7: 1047–1054; © Wiley-VCH.)

The equation for the chronopotentiogram for both PSA and CCSA of adsorbed molecules is

$$E = E^{\circ} + \frac{RT}{nF} \ln \frac{\tau - t}{t} \quad [21]$$

An interesting effect is obtained when stripping an adsorbed analyte if an electroactive species in solution is simultaneously being oxidized or reduced. For example, if an adsorbed molecule was being reduced with a constant current in the presence of dissolved oxygen, a part of the current applied to the cell goes into reducing the dissolved oxygen. Effectively, this means that less current is available to reduce the adsorbate and consequently, from eqn [19], an increased stripping time is observed. An example is shown in Figure 4. This enhancement of the stripping time can be quantified.

## Applications

The applications of chronopotentiometric stripping are identical to those of stripping voltammetry. For

example, elements such as Bi, Cd, Cu, Ga, In, Pb, Mn, Tl, Zn, Co, Ni, Fe, and Se have been determined by PSA or CCSA at mercury film electrodes. Additional elements such as Na and K can be determined from aprotic solvents. Other elements such as Hg, Ag, As, Sb, and Sn can be determined at gold electrodes. Detection limits below the microgram per liter level are generally obtained following an appropriate preconcentration period. Many stripping voltammetric methods using adsorptive preconcentration to quantify metal ion complexes or organic molecules have been repeated using PSA or CCSA.

While the applications of chronopotentiometric stripping are identical to stripping voltammetry, chronopotentiometric methods may be preferable for certain sample types. The current widespread use of PSA and derivative PSA is mainly due to the efforts of Jagner and co-workers, which centered on the PSA determination of metal ions following their potentiostatic deposition at a mercury thin film electrode followed by a chemical oxidation with either dissolved oxygen or mercury (II). Much of this early work focused on analysis of metal ions in what would normally be considered difficult sample matrix such as wine and fruit juice. PSA is suitable for low ionic strength and low conductivity solutions and, when employing electrolytic preconcentration, is less affected by the presence of organic compounds in the sample than in stripping voltammetry or CCSA. Thus, PSA is preferable in situations such as metal analysis in the field where sample pretreatment such as deoxygenation or removal of organic matter is necessary to improve accuracy and lower detection limits or for metal analysis in samples containing large amounts of organic material such as wine or blood.

### Introduction

The platinum group metals (Ru, Rh, Pd, Os, Ir, and Pt), Ag, and Au are called ‘precious’ or ‘noble’ metals. Nobility and catalytic activity are unique properties of precious metals, that result in a wide range of applications, such as catalysts in various industrial fields, in electronic industries, and in jewelry. The chemical and physical properties of each precious metal are shown in Table 1. The determination of precious metals attracted the interest of analysts and developed rapidly because these metals are valuable and rare, and also very important for many products. Their concentration levels are very low in many natural sources, metallurgical intermediates, and environmental samples. Furthermore, precious metals are collectively handled in the analytical chemistry field, because of the close resemblance of their chemical properties and behavior. Precious metals are the subproducts in copper, zinc, or lead smelting and refining, which is the most important source of precious metals. Whereas many analytical methods for the ultratrace determination of precious metals in environmental or biological samples were recently published with the development of high-sensitivity analytical instruments, the classical fire-assay has been widely applied for the accurate determination of expensive precious metals.

### International Standard Method

The international standard method for the determination of precious metals has been mainly discussed in ISO/TC183 (copper, lead, and zinc ores and concentrates) and ISO/TC174 (Jewelry). Table 2 shows

the ISO international standard methods published or discussed. Accurate sampling methods, for example, fire assay, titrimetric method, and/or gravimetric method are regulated in almost all international standards for precise and true determination, because of international trading of expensive precious metals. Another method for the determination of precious metals content is by subtraction of the total content of impurities in the sample from 100%, which is also regulated. In these cases, atomic absorption spectrometry (AAS) and/or inductively coupled plasma-atomic emission spectrometry (ICP-AES) is utilized for the final detection.

### Sample Decomposition (Sample Preparation)

Sample decomposition for the determination of precious metals is very difficult, because of their high chemical stability and low content in samples.

Fire assay is the classical sample decomposition method. This method is also used due to its merit of accuracy, when collecting the precious metals from various sulfide ores, or when collecting the precious metals from a complicated matrix. Although lead fire assay is used for the collection of Au, Ag, Pt, Pd, Rh, etc., Os is volatilized by the lead fire assay method. Moreover, the recovery of Ru and Ir is poor. The nickel sulfide fire assay is used for a large number of precious metals, but the recovery of Au is quite low.

Chlorination technique has been developed to make the precious metals water soluble; that is, effective for a low concentration sample, alloy, or sulfide mineral. Chlorination consists of both dry and wet methods. Chlorination gives a low reagent blank, and is used in combination with high-sensitivity detection. In the wet chlorination method, the samples are pressurized in a closed vessel with an oxidizing agent and hydrochloric acid, and dissolved

in hydrochloric acid. The advantage of this method is that the recovery of precious metals is quantitative without losing Ru and Os.

The acid decomposing method is widely used in many sample treatments. Generally, according to the matrices of a sample, a mineral acid or its mixture is used in a vessel that is either an open or a closed system. A hot plate system and/or a microwave oven are commonly utilized for sample digestion. In the case of an open vessel, the recovery of Os is poor because of volatilization.

Alkali fusion is used as a digestion technique for putting a persistent sample into solution. Sodium peroxide is mainly used as the flux for analyzing the precious metals. However, in the case of direct fusion of a metal or a sulfide sample, preliminary oxidization is necessary to perform fusion completely and safely.

## Separation and Concentration

Solvent extraction, solid–liquid sorption, ion exchange, and precipitation methods are commonly used for the separation or preconcentration of precious metals from various matrices.

### Fire Assay

The fire-assay method described above has some advantages as the separation and preconcentration method of precious metals. It is useful where large samples are required owing to their extremely low

concentrations in some materials and the heterogeneity of ores containing these metals. Lead, copper, copper–iron–nickel alloy and nickel sulfide have been used as collectors. Lead fire assay is an effective and widely used technique for the preconcentration of Au, Ag, Pt, and Pd when the concentrations of the last two elements are low. Nickel sulfide fire assay is very effective for the collection of precious metals. By reducing the button size to below 1 g, the precious metals are successfully determined directly in the button with inductively couple plasma-mass spectrometry (ICP-MS). For understanding the effects of fusion charge composition on the collection of precious metals into a minimized NiS button, the extraction ratio  $E$ , is expressed as  $E = (m_{\text{sample}} + m_{\text{flux}}) / (m_{\text{Ni}} + m_{\text{S}})$ , where  $m$  is the mass of the component indicated by the subscript.  $E > 30$  only due to the effect of the sample composition, particularly its sulfur content. Antimony fire assay was derived prior to concentrate precious metals from samples with simpler compositions. The separation of precious metals, including Os, from antimony can be achieved by cupellation.

### Gold

Au can be readily precipitated from extremely dilute, acid solutions by such reducing agents as tin(II) chloride, sulfurous acid plus hydrazine hydrochloride, Zn, and Mg if a suitable collector is used. Tellurium is very useful as a collector. The precipitate of

elemental tellurium, produced by reduction with tin(II) chloride, contains Au as telluride. If tellurium must be removed, the precipitate can be ignited strongly to volatilize tellurium oxide. Pd, Pt, Hg, and As will be co-precipitated with Au. Au can also be precipitated with various organic reducing agents such as Metol, *p*-phenylene diamine, and hydroquinone in hot 1 mol l<sup>-1</sup> HCl. Pd, Pt, Te, and Se are not precipitated under these conditions, and Pd and Pt at least show less tendency to contaminate in the precipitation of Au. One microgram of Au can be precipitated quantitatively with *p*-dimethylaminobenzylidenerhodanine or 2-mercaptobenzothiazole from 50 ml of dilute aqua regia or dilute HNO<sub>3</sub> solution. Ag, Hg, and Pd are also precipitated nearly quantitatively. Au(III) as chloroaurate is strongly adsorbed on a strongly basic anion-exchange resin from HCl solutions at any acid concentration. This behavior has been utilized for the separation of Au in seawater and of traces of Au in copper. Because a suitable eluant for Au has not been found, the resin is ignited in an alumina crucible at as low a temperature as possible. Au(III) has been separated from Ni, Cu, and Fe(III) by adsorption of Au on Dowex 1-X8 from 0.5 mol l<sup>-1</sup> HCl and elution with 0.3 mol l<sup>-1</sup> thiourea in 0.1 mol l<sup>-1</sup> HCl at 50°C. Au and Pt metals can be separated from base metal (Fe(III), Cu, Ni) by adsorption of the base metals on strongly acidic cation-exchange resin, Dowex 50W-X8, from diluted HCl solution of pH 1.0–1.5. A medium of 0.1 mol l<sup>-1</sup> HCl in 60% (v/v) acetone serves the same purpose. Au can be separated from Pt, Ir, Pd, and Rh by adsorption of Au on Dowex 50W-X8 from 6 mol l<sup>-1</sup> HBr – 0.0035 mol l<sup>-1</sup> bromine. Solvent extraction is one of the important techniques for the separation and preconcentration of precious metals. Many common extractants such as 4-methyl-2-pentanone (IBMK), tributyl phosphate (TBP), and trialkylphosphine oxide (TOPO) are still widely used. The extractability of chloroauric acid from hydrochloric acid medium, and of bromoauric acid from hydrobromic acid, by ether and ethyl acetate provides not only a method for isolating small amounts of Au but also a method for separating it from most of the precious group metals as well as other elements. The extraction coefficient (ether/aqueous phase) has a value of ~50 for 3–6 mol l<sup>-1</sup> HCl with macro concentrations of Au. Bromoauric acid is a better extraction form for Au than chloroauric acid. Isopropyl ether is a more satisfactory solvent than ethyl ether, ethyl acetate, or IBMK. Clark *et al.* reported an IBMK–amine synergistic iodide complex (MAGIC) extraction system for use in geological exploration samples. The method involves extraction of halides, mostly iodide,

complexes of metals into an organic phase that contains Aliquant-336, tricaprylyl tertiary amine, and IBMK. The extraction was carried out in HCl between 2.25 and 4.2 mol l<sup>-1</sup> in the presence of MAGIC salt solution composed of potassium iodide, bromide, chloride, and L-ascorbic acid. Precious metals containing Au, Pd, and Pt can be quantitatively extracted into organic solution. The organic extract can be analyzed directly by AAS or ICP-AES. For samples with high Fe content, extraction of iodide or bromide complexes into IBMK as ion associates with long-chain aliphatic polyamines is a promising method for multielement concentration.

### Silver

Precipitation of Ag as chloride, or better as bromide, with a slight excess of precipitant may be a useful method of separation. Traces of Ag have been separated by thallium iodide as the collector. The precipitation can be dissolved in diluted H<sub>2</sub>SO<sub>4</sub>–H<sub>2</sub>O<sub>2</sub> solution. A widely applicable method for the isolation of traces of Ag consists in co-precipitation with elemental tellurium formed by adding tin(II) chloride to 2 mol l<sup>-1</sup> HCl solution of the sample containing Te(IV) (see above). The extraction constant of primary Ag dithizonate is such that Ag can be extracted quantitatively from 6 mol l<sup>-1</sup> H<sup>+</sup> solution by the use of 0.001% (w/v) dithizone solution in carbon tetrachloride. Anions such as halides and thiocyanates that form slightly soluble or complex Ag salts must be absent when extraction is made in mineral acid medium. Other metals extracted at high acidity are Pd, Au, and Hg. Copper will also be extracted.

### Platinum

Minute amounts of Pt can be separated from almost all of the non-noble elements by precipitation with tin(II) chloride from HCl solution containing a small amount (< 1 mg) of tellurium(IV). Au, Ag, Pd, Rh accompany Pt, the first three usually quantitatively, and Rh incompletely but in large amount. Ir appears to be incompletely precipitated. Milligram amounts of Pt, Pd, Rh, and Ir can be separated from base metals by complexing the Pt metals with NaNO<sub>2</sub> and precipitating the latter at pH 7. The separation of Au from Pt can be effected by precipitating Au with a reagent such as oxalic acid, sulfur dioxide, nitrous acid, or hydroquinone, which do not reduce Pt to the metals, but a reprecipitation is required. Ag may be separated by precipitation as chloride with slight excess of HCl if the precipitate is dissolved in ammonia and again thrown down by acidification to release co-precipitated Pt. Pt will be present as ammine complexes in the filtrate from the reprecipitated

AgCl; in order to convert it to chloroplatinic acid, it is necessary to evaporate the solution, destroy  $\text{NH}_4\text{NO}_3$  with HCl and  $\text{HNO}_3$ , evaporate to fumes with  $\text{H}_2\text{SO}_4$ , and after eliminating most of the latter, treating with dilute aqua regia.

Anion-exchange chromatography of chloro-complexes of the Pt metals is especially useful. After adsorption on a strongly basic anion-exchange resin Amberlite IRA-400, Rh is eluted with  $2 \text{ mol l}^{-1}$  HCl, Pd with  $9 \text{ mol l}^{-1}$  HCl, and Pt with  $2.4 \text{ mol l}^{-1}$   $\text{HClO}_4$ . The Pt metals plus Au can be separated from Fe, Co, Ni, and Cu by extracting the noble metals with 4-octylaniline in diisobutyl ketone or the other organic solvents from dilute ( $3 \text{ mol l}^{-1}$ ) HCl medium. The Pt metals are back-extracted with  $7 \text{ mol l}^{-1}$   $\text{HClO}_4$ , but Au is not back-extracted. Pt and Pd also can be separated from Rh and Ir by extracting the former pair with sodium diethyldithiocarbamate and chloroform or IBMK from HCl–KI solution. Ethyl ether extraction of Fe(III), Au(III), and other metals from HCl solution may be of value at times for removal of large amounts of these from Pt(IV).

### Palladium

Minute amounts of Pd can be co-precipitated with elemental tellurium obtained by reduction of a tellurite with tin(II) chloride or similar strong reducing agents. The slight solubility of Pd(II) dimethylglyoximate and other dioximates in dilute HCl solution enables fairly small amounts of Pd to be separated from most other metals except Au (Pt tends to contaminate Pd dimethylglyoximate). Such precipitation fails at the low Pd concentrations frequently encountered, but  $<1 \text{ mg l}^{-1}$  of Pd can be co-precipitated with Ni dimethylglyoximate from a solution (pH 6.5) containing tartrate,  $(\text{NH}_3\text{OH})\text{Cl}$ , and acetate. Pd can be separated from large amounts of Fe, Ni, and Cu on a strongly basic anion-exchange resin at pH  $\sim 1.5$ ; the chloro complexes of Pd, Pt, Rh, and Ir pass through the column. Chloroform extraction of Pd(II) dimethylglyoximate provides the most selective separation of Pd from other elements. This extraction has not been systematically studied, but it is known that Pd can be quantitatively extracted from  $0.2\text{--}0.3 \text{ mol l}^{-1}$  HCl or  $\sim 0.5 \text{ mol l}^{-1}$   $\text{H}_2\text{SO}_4$  solutions. Fe(III) is reported to hinder the extraction of Pd. Extraction with IBMK from  $\sim 7.5 \text{ mol l}^{-1}$  HCl removes Fe(III), Mo(VI), etc.

### Rhodium

In the systematic macroanalysis of the platinum group metals, Os and Ru are first separated by volatilization of the tetraoxides, and Pd, Rh, and Ir are then precipitated as hydrous oxides in the

presence of bromate by adding  $\text{NaHCO}_3$ . The hydrolytic precipitation of Rh is complete at pH 6. A reprecipitation of the hydrous rhodium oxide is required to free it from Pt. Palladium is removed as the dimethylglyoximate, and Rh is then precipitated as metal, and thus separated from Ir, by reduction with  $\text{TiCl}_3$  in hot  $\text{H}_2\text{SO}_4$  solution. The Rh precipitate must be dissolved and reprecipitated to eliminate the small amount of Ir that has been carried down. The microgram quantities of Rh can be separated from  $2 \text{ mol l}^{-1}$  HCl by reduction with  $\text{TiCl}_3$  in the presence of Pd as collector. Elements precipitated with Rh include Pt, Ir (at least partly), Au, Ag, Te, Se, and Hg. Rh can be separated from Ir in HCl or  $\text{H}_2\text{SO}_4$  solution by reducing the former to the metal by boiling with Sb or Cu powder. Pt, Pd, and Rh (plus Ru and Ir) have been separated from each other by using organic co-precipitants including  $\text{SCN}^-$ -diantipyrinylmethane. A useful separation of Rh and other Pt metals from base metals (Cu, Fe, Ni) is based on the adsorption of the base metals on the cation-exchange resin Dowex 50W-X8 from HCl solution of pH 1.0–1.5 and nonadsorption of the Pt metals. Rh(III) can be extracted into 1-butyl-3-methylpyrazole in toluene from  $0.01 \text{ mol l}^{-1}$  HCl medium and separated from Pt(IV), Ir(III,IV), and many base metals including Fe(III), Cu, and Ni. Pd(II) is also extracted and Au(III) is partially extracted. Pt and Pd also can be separated from Rh and Ir by extracting the former pair with Na diethyldithiocarbamate and chloroform from HCl–KI solutions, with IBMK from HCl–KI solution, or with trioctylammonium chloride in toluene from  $\text{NaNO}_2$  solution. Pt and Pd are also extracted with trioctylamine in benzene from  $4\text{--}6 \text{ mol l}^{-1}$  HCl; Rh remains in the aqueous phase.

### Ruthenium

Ru in  $0.2 \text{ mol l}^{-1}$  HCl has been co-precipitated with  $\text{Re}_2\text{S}_7$  by  $\text{H}_2\text{S}$  under pressure. Ag has been separated from Ru, Rh, Pd by precipitation as AgCl (purified by dissolution in aqueous ammonia and reprecipitation). Ru can be separated from base metals (Cu, Fe, and Ni) by cation-exchange resin using pH 1.0 HCl. Ru(III) can be separated from Rh(III) by adsorption of Ru thiocyanate on polyurethane foam. The isolation and separation of Ru can be simplified by extracting  $\text{RuO}_4$  with an immiscible organic solvent instead of volatilizing it.  $\text{RuO}_4$  is soluble in inert solvents such as chloroform and carbon tetrachloride, which will extract very few inorganic substances under any conditions and still fewer from an  $\text{H}_2\text{SO}_4$  or  $\text{HNO}_3$  solution. The main problems arising in the analytical application of this extraction concern the oxidation of Ru to the +8 state and return of Ru

from carbon tetrachloride to an aqueous phase. AgO is very suitable for oxidation of Ru(III or IV) to Ru(VIII) in  $\text{H}_2\text{SO}_4$  or  $\text{HNO}_3$  medium. Ru can be removed quantitatively from the carbon tetrachloride phase by shaking with an aqueous solution of  $\text{SO}_2$ . The back-extraction is slow and 2 h of shaking is required for submicrogram quantities of Ru. Os can be removed by carbon tetrachloride extraction of  $\text{OsO}_4$  before oxidation of Ru to  $\text{RuO}_4$ . Iron(III) can be removed by extraction with ethyl ether from  $6 \text{ mol l}^{-1}$  HCl and with isopropyl ether from  $8 \text{ mol l}^{-1}$  HCl. Ru can be isolated by oxidizing to  $\text{RuO}_4$  in acid solution and volatilizing (distilling) this compound (b.p.:  $130^\circ\text{C}$ ). The distillation effects a separation from almost all other metals except Os. A strong oxidizing agent is needed to convert Ru in the +3 or +4 state to the +8 state. Hot perchloric acid is one of the good oxidizing agents. Os can be separated from Ru by boiling a  $5 \text{ mol l}^{-1}$   $\text{HNO}_3$  solution after preliminary oxidation with  $\text{KMnO}_4$ . Only Os is volatilized as  $\text{OsO}_4$ . Nitric acid is then eliminated by evaporation of the solution to dryness followed by evaporation several times with HCl. Finally, chloride is removed by fuming with  $\text{H}_2\text{SO}_4$ , after which distillation of Ru as  $\text{RuO}_4$  can be carried out.

### Iridium

In a standard method for separating the Pt metals from each other, Ir is precipitated as the hydrous dioxide by adding  $\text{NaHCO}_3$  to a boiling acid solution containing bromate until a pH of 6 is reached. Pd and Rh are also precipitated, but not Pt(IV); Os and Ru must be removed from the solution by volatilization of tetraoxides before the hydrolytic precipitation is made. Palladium is then precipitated from the (acid) solution of the hydrous oxide precipitate as dimethylglyoximate followed by precipitation of Rh with  $\text{TiCl}_3$  in the filtrate. Some Ir is carried down by metallic Rh, and the precipitate must be dissolved in hot concentrated  $\text{H}_2\text{SO}_4$  and the precipitation repeated. Ir is thus left with Ti, which is precipitated with cupferron (reprecipitation is necessary). A fairly satisfactory separation of microgram quantities of Ir from Rh can be obtained by boiling  $\text{H}_2\text{SO}_4$  solution with Sb powder; Rh is precipitated, whereas Ir remains completely in solution. Freshly reduced Cu powder also can be used as a precipitant (reductant) for Rh in  $1 \text{ mol l}^{-1}$  HCl solution; Ir remains quantitatively in solution. Ir, Pt, Pd, and Rh can be precipitated by thiourea and they can be separated from Cu, Fe, Ni, Pd, Pt(IV), Ir(IV), and Rh(III) as chloro complexes can be separated from base metals (Cu, Fe(III), Ni, etc.) by use of the cation-exchange resin Dowex 50W-X8. The base metals are adsorbed from

HCl solutions of pH 1.3–1.5, whereas the Pt metals are not. Ir and Rh can be separable from each other in thiourea solution by a cation exchanger. An anion-exchange method for separating Rh from Ir is based on the strong affinity of chloroiridate(IV) for the anion exchanger in contrast to the relatively weak affinity of chlororhodate(III). The resin is previously washed with water and Ce(IV) solution in  $0.8 \text{ mol l}^{-1}$  HCl. After adsorption from  $0.8 \text{ mol l}^{-1}$  HCl solution, Rh is eluted with  $0.8 \text{ mol l}^{-1}$  HCl containing Ce(IV) to retain Ir(IV). Ir is removed from the resin in a Soxhlet extractor with  $6 \text{ mol l}^{-1}$  HCl. Ir can be separated from Rh by TBP extraction of Ir(IV) from  $\sim 6 \text{ mol l}^{-1}$  HCl.

### Osmium

Losses of Os can occur during evaporation of hydrochloric acid solution of chloroosmate(IV) and during fusion of geomaterials. Os(IV) can be isolated by hydrous precipitation of the hydrous oxide. A 10%  $\text{NaHCO}_3$  solution is added to the boiling solution until a precipitate appears and suddenly coagulates. Os(IV) can be separated from base metals by adsorption of the latter on a strong-acid cation-exchange resin (Dowex 50W-X8) from an HCl solution of pH 0.8–1.5. Os(VIII) oxide can be extracted from aqueous medium by carbon tetrachloride and chloroform and also distilled (see Ru section). The distillate is collected in  $6 \text{ mol l}^{-1}$  HCl saturated with  $\text{SO}_2$ .

## Detection Method for Each Precious Metal

### Gold

Au content in sulfide ores is determined by fire assay using scorification or cupellation. Crucible fusion of the samples mixed with a litharge-based flux that, under reducing conditions, collects the precious metals in a metallic lead button. Oxidizing fusion helps the base metals present in the lead button to be substantially separated from the precious metals. Cupellation produces a bead largely comprising an Ag–Au alloy with small quantities of other metals. Au is separated from the primary bead by treatment with nitric acid. The Au prill is weighed. Au prills with a mass less than  $50 \mu\text{g}$  are dissolved in aqua regia and the Au is determined by AAS. Ag is determined in the parting solution by AAS. All residues are retreated to maximize the recovery of Au and Ag. The addition of collectors for either Au or Ag is not required, as both metals are present in sufficient amounts to be readily visible after the cupellation stage. The second bead is dissolved in acids followed by analysis of both metals by AAS. Contamination

by Au and Ag impurities in the reagents is corrected for by fusing the reagents without the test portion. Au in aqueous solutions can be determined as Au metal by using an appropriate reduction agent and igniting at 800°C. Oxalic acid is used for separating Au and the other platinum group metals. Tin(II) chloride, hydrobromic acid, and Rhodamine B are utilized as the chromogenic reagent for spectrophotometric determination of Au. Radiations of wavelengths 242.8 and 267.6 nm are used for the analytical line for atomic absorption spectrometric detection of Au. Each metal's sensitivity (1% absorption) is 0.2 and 0.4 mg l<sup>-1</sup> with Air-C<sub>2</sub>H<sub>2</sub> flame. There is no interference from other platinum group metals, but iron and copper interfere. The characteristic mass in picogram/0.0044 absorbance is 13 in GF-AAS. The most sensitive spectral line for ICP-AES is 242.795 nm. The detection limit is ~3 ng l<sup>-1</sup>. Mass number = 197 is used for ICP-MS detection. The detection limit is ~0.0005 ng l<sup>-1</sup>. TaO<sup>+</sup> (= 197) interferes with Au determination. The current popular stripping voltammetric for the determination of Au are based on the chloro-complex with gold on the carbon paste electrode. Au can be determined in the range from 5 to 250 nmol l<sup>-1</sup>. Neutron activation analysis (NAA) combined with radiochemical separation is a very sensitive technique. The Au in the sample is subject to the nuclear reaction: <sup>197</sup>Au(n,γ)<sup>198</sup>Au. The intensity from <sup>198</sup>Au radionuclide (*t*<sub>1/2</sub> = 2.7 days) that corresponds to the concentration of Au in the sample is measured. The sensitivity is 10<sup>-6</sup>–10<sup>-3</sup> μg. The interferences include Ag, Pt, and Br, which might be critical for the determination of Au at the nanogram per gram level. X-ray fluorescence spectrometry (XRF) is able to give a rapid estimation of the sample composition and often without damaging the sample. The accuracy, however, is not good enough to satisfy the official requirements in the analysis of jewelry, etc. The rapid analysis by XRF is utilized in routine quality control.

### Silver

Gravimetric method such as AgCl or fire assay is used. Gay-Lussac method involves the titration of Ag with NaCl and/or KBr in acid solution. The endpoint is taken as the point at which no further precipitation of silver halide is observed upon the addition of more precipitant. Fajans method is based on the precipitation of Ag with chloride or bromide ions, using an adsorption indicator to detect the endpoint. Rhodamine 6G or dichlorofluorescein is used as the adsorption indicators. Volhard method is based on the titration of Ag with potassium or sodium thiocyanate to form insoluble silver thiocyanate. This titration is

carried out in dilute acid medium in the presence of a small quantity of ferric ion as the indicator. For accurate work, an indicator blank must be determined and subtracted. The most generally suitable reagents at the present time for the photometric determination of small amounts of Ag are dithizone and *p*-dimethyl- or *p*-diethyl-amminobenzylidenerhodamine. Neither is specific for Ag. Au and Pd react with both. Small amount of Hg can be tolerated in the direct rhodamine method but not in dithizone. In practical analysis, separations will usually be required before dithizone or rhodamine can be applied. The nephelometric determination of Ag as chloride is also used as a conventional method. Radiations of wavelengths 328.1 and 338.3 nm are used for the analytical line for atomic absorption spectrometric detection of Ag. Each metal's sensitivity (1% absorption) is 0.05 and 0.15 mg l<sup>-1</sup> with Air-C<sub>2</sub>H<sub>2</sub> flame. The characteristic mass in picogram/0.0044 absorbance is 1.4 in GF-AAS. The detection limit is ~1.5 ng l<sup>-1</sup>. The most sensitive spectral line for ICP-AES is 328.068 nm. The detection limit is ~1 ng l<sup>-1</sup>. Mass number = 107 is used for ICP-MS detection. The detection limit is ~0.0009 ng l<sup>-1</sup>. ZrO<sup>+</sup> (= 107) interferes in Ag determination. The popular stripping voltammetric method for the determination of Ag is based on nitric acid media on a carbon paste electrode. Au can be determined in the range from 4 to 20 nmol l<sup>-1</sup>. The Ag in the sample is subject to the nuclear reaction: <sup>107</sup>Ag(n,γ)<sup>108</sup>Ag or <sup>109</sup>Ag(n,γ)<sup>110</sup>Ag. The sensitivity is 10<sup>-4</sup>–10<sup>-2</sup> μg. XRF is able to give a rapid estimation of the sample composition and often without damaging the sample.

### Platinum

There are no selective gravimetric reagents for the determination of Pt. The element must first be isolated from interfering metals. Ammonium chloride or sodium formate is the acceptable method for gravimetric procedure. The two important reagents for the spectrophotometric determination of Pt are tin(II) chloride and *p*-nitrosodimethylaniline. The advantage of the latter is its sensitivity. It is far less selective than the tin(II) chloride method and requires close control of conditions of color development. Radiation of wavelength 266.0 nm is used for the analytical line for atomic absorption spectrometric detection of Pt. The sensitivity (1% absorption) is ~0.05 mg l<sup>-1</sup> with Air-C<sub>2</sub>H<sub>2</sub> flame. The characteristic mass in picogram/0.0044 absorbance is 100 in GF-AAS. The detection limit is ~10 ng l<sup>-1</sup>. The most sensitive spectral line for ICP-AES is 265.95 nm. The detection limit is ~2 ng l<sup>-1</sup>. Mass number = 195 is used for ICP-MS detection. The

detection limit is  $\sim 0.0007 \text{ ng l}^{-1}$ .  $\text{HfO}^+$  ( $=195$ ) interfere Pt determination. The current popular stripping voltammetric methods for the determination of Pt are based on the catalytic effect of the formazone (a condensation product of formaldehyde and hydrazine) complex with platinum on the developed hydrogen at a mercury electrode. Pt can be determined polarographically. More sensitive approaches involve adsorption preconcentration of the platinum complex on a hanging mercury drop electrode, which is followed by cathodic stripping. Earlier stripping voltammetric methods for determining Pt have been based on the masking of the sulfide or thiourea peak by platinum or on the deposition of platinum on a graphite or glassy-carbon electrode from solutions containing  $\text{PtCl}_4^{2-}$  and  $\text{PtCl}_6^{2-}$  ions, followed by anodic stripping voltammetry. The sensitivity of these methods is not high (detection limit  $\sim 10^{-8} \text{ mol l}^{-1}$ ). On irradiation in a thermal neutron flux, the platinum in the sample is subject to the nuclear reaction:  $^{198}\text{Pt}(n,\gamma)^{199}\text{Pt} \rightarrow ^{199}\text{Au}$ . The intensity of a  $\gamma$ -peak ( $E_\gamma = 158.9 \text{ keV}$ ) from  $^{199}\text{Au}$  radionuclide ( $t_{1/2} = 3.15 \text{ days}$ ) that corresponds to the concentration of Pt in the sample is measured. The sensitivity is  $10^{-2} \sim 1 \mu\text{g}$ . The irradiated sample is decomposed and mixed with the carrier (Au), which is separated using the methods described in the section on gold. The rapid analysis by XRF is utilized in routine quality control.

### Palladium

Dimethylglyoxime in an alcohol solution is generally used as the gravimetric reagent. When a large amount of palladium is to be precipitated, the water-soluble sodium salt is more convenient. The gravimetric determination of palladium as the diiodide is not selective as with dimethylglyoxime, but quicker and at least as accurate. The precipitate is very stable, filters readily, and can be easily reduced to the metal. Palladium may be readily reduced to the metal by formate ion. This is best done in a 20% sulfuric acid medium since hydrochloric acid tends to redissolve the metal. The iodide titration as palladium iodide is one of the most acceptable methods. The isolation of palladium before titration is essential. Compounds containing the *p*-nitrosophenylamino group form strongly colored complexes with Pd(II). Both *p*-nitrosodimethylaniline and *p*-nitrosodiphenylamine may be used for the photometric determination of Pd. Radiation of wavelength 283.3 nm is used for the analytical line for atomic absorption spectrometric detection of palladium. The sensitivity (1% absorption) is  $\sim 0.01 \text{ mg l}^{-1}$  with Air-C<sub>2</sub>H<sub>2</sub> flame. The characteristic mass in picogram/0.0044

absorbance is 24 in GF-AAS. The detection limit is  $\sim 4 \text{ ng l}^{-1}$ . The most sensitive spectral line for ICP-AES is 248.89 nm. The detection limit is  $\sim 6 \text{ ng l}^{-1}$ . Mass number = 106 is used for ICP-MS detection. The detection limit is  $\sim 0.002 \text{ ng l}^{-1}$ .  $\text{Cd}^+$  ( $=106$ ) and  $\text{ZrO}^+$  ( $=106$ ) interfere in Pd determination. The Pd in the sample is subject to the nuclear reaction  $^{108}\text{Pd}(n,\gamma)^{109}\text{Pd}$ . The sensitivity is  $10^{-4} - 10^{-2} \mu\text{g}$ . Because of low content in natural samples, radiochemical neutron activation analysis (RNAA) is utilized instead of instrumental neutron activation analysis (INAA).

### Rhodium

There are no specific precipitants for Rh. Rh is precipitated as metal by hydrazine in alkaline solution. The hydrolytic procedure is an acceptable gravimetric procedure. Few satisfactory photometric methods are available for Rh. The tin(II) chloride method is generally preferred. The sensitivity can be increased by carrying out the reaction in the presence of bromide or iodide. Radiation of wavelength 343.5 nm is used for the analytical line for atomic absorption spectrometric detection of Rh. The sensitivity (1% absorption) is  $\sim 0.02 \text{ mg l}^{-1}$  with Air-C<sub>2</sub>H<sub>2</sub> flame. The characteristic mass in picogram/0.0044 absorbance is 12 in GF-AAS. The detection limit is  $\sim 100 \text{ ng l}^{-1}$ . The most sensitive spectral line for ICP-AES is 369.24 nm. The detection limit is  $\sim 3 \text{ ng l}^{-1}$ . Mass number = 103 is used for ICP-MS detection. The detection limit is  $\sim 0.009 \text{ ng l}^{-1}$ .  $\text{SrOH}^+$  ( $=103$ ) and  $\text{SrO}^+$  ( $=103$ ) interfere in Rh determination. The complexity of interferences negates the possibility of using electrochemical methods in routine quantitative work with Rh. The Rh in the sample is subject to the nuclear reaction  $^{103}\text{Rh}(n,\gamma)^{104\text{m}}\text{Rh}$ . The sensitivity is  $10^{-5} - 10^{-3} \mu\text{g}$ . The sensitivities obtained in NAA are several orders of magnitude lower than by other approaches, but it is hard to achieve them on real samples due to the complexity of interferences. XRF is often favored, when applicable, because of the speed of analysis. However, the sensitivity of XRF is relatively poor and limited to samples containing milligram or higher amounts. Lead interferes in Rh determination with XRF. A number of procedures have been developed for XRF analysis of Rh after separation and preconcentration by fire assay or by resin-impregnated filter paper.

### Ruthenium

Ru may be quantitatively precipitated as a hydrous oxide. It is necessary to reduce the distilled Ru(IV) oxide to the four-valent state. Sulfite and alcohol are

often used as reducing agents. There is no acceptable volumetric procedure for the determination of Ru. In some early studies of the oxidation states of dissolved ruthenium halides, Ru(IV) was determined directly by titration with tin(II) chloride as indicated by the color change from red-brown to light rose, and more accurately by addition of excess tin(II) chloride and back-titration with iodine in the presence of starch. Strongly colored procedures are obtained when an acid solution of a ruthenium salt is heated with thiourea. 1,4-Diphenylthiosemicarbazide forms a red-violet chloroform-extractable complex with Ru. In the presence of hydroxylammonium chloride, Ru(III or IV) reacts with phenanthroline to form yellow tris(1,10-phenanthroline) Ru(II) ion. The reaction is slow even at 100°C and after 2 h at this temperature the reaction is ~97% complete. Radiation of wavelength 372.8 nm is used for the analytical line for atomic absorption spectrometric detection of Ru. The sensitivity (1% absorption) is  $\sim 0.06 \text{ mg l}^{-1}$  with Air-C<sub>2</sub>H<sub>2</sub> flame. The characteristic mass in picogram/0.0044 absorbance is 32 in GF-AAS. The most sensitive spectral line for ICP-AES is 378.89 nm. The detection limit is  $\sim 60 \text{ ng l}^{-1}$ . Mass number = 102 is used for ICP-MS detection. The detection limit is  $\sim 0.001 \text{ ng l}^{-1}$ . Pd<sup>+</sup> (=102) and SrO<sup>+</sup> (=102) interfere in Ru determination. The Ru in the sample is subject to the nuclear reaction  $^{102}\text{Ru}(n,\gamma)^{103}\text{Ru}$ . The sensitivity is  $10^{-3}$ – $10^{-1} \mu\text{g}$ . Because of low content in natural samples, RNAA is utilized instead of INAA.

### Iridium

The hydrolytic procedure in combination with purification by chlorination is an acceptable gravimetric procedure. The Ir solution must be free from large concentrations of base metals and other Pt metals, with the exception of Pt metals. The acidic solution containing Ir is treated with sodium bromate while boiling and the solution is neutralized with addition of sodium bicarbonate solution. The precipitate is filtered, dried, and ignited. Tin(II) chloride-hydrobromic acid method will usually be preferred to other photometric methods for Ir. Radiation of wavelength 264.0 nm is used for the analytical line for atomic absorption spectrometric detection of Ir. The detection limit is  $\sim 1.0 \text{ mg l}^{-1}$  with N<sub>2</sub>O-C<sub>2</sub>H<sub>2</sub> flame. The characteristic mass in picogram/0.0044 absorbance is 275 in GF-AAS. The detection limit is  $\sim 50 \text{ ng l}^{-1}$ . The most sensitive spectral line for ICP-AES is 322.08 nm. The detection limit is  $\sim 70 \text{ ng l}^{-1}$ . Mass number = 193 is used for ICP-MS detection. The detection limit is  $\sim 0.0006 \text{ ng l}^{-1}$ . HfO<sup>+</sup> (=193) interferes in Ir determination. INAA is a highly sensitive

method of analysis with which low and sub-nanogram per gram limits of detection can be achieved. Ir in the sample is subject to the nuclear reaction  $^{191}\text{Ir}(n,\gamma)^{192}\text{Ir}$  or  $^{193}\text{Ir}(n,\gamma)^{194}\text{Ir}$ . The sensitivity is  $10^{-5}$ – $10^{-2} \mu\text{g}$ .

### Osmium

Os may be determined gravimetrically after precipitation as the hydrous oxide. The procedure is similar to that used for Ru, with difference that all ignitions must be done in hydrogen or an inert atmosphere to avoid loss as Os(VIII) oxide. The hydrous oxide is precipitated within the pH range 1.5–6.3 by adjusting the boiling solutions with sodium bicarbonate additions. A number of volumetric methods have been used for the determination of Os with accuracy, in some cases, as good as a few tenths of 1%. In most cases sealed-tube reactions are used to force the reactions. Hydrazine sulfate, tin(II) chloride, and iodide have been used to titrate Os(VIII). These methods are only applied to the analysis of pure salts. Thiourea is an old and well-established photometric reagent for Os, but it is not very sensitive. When really small quantities of Os must be determined, the catalytic method based on the reaction between As(III) and Ce(IV) will be chosen. Radiation of wavelength 305.9 nm is used for the analytical line for atomic absorption spectrometric detection of Os. The detection limit is  $\sim 0.4 \text{ mg l}^{-1}$  with N<sub>2</sub>O-C<sub>2</sub>H<sub>2</sub> flame. The characteristic mass in picogram/0.0044 absorbance is 1400 in GF-AAS. The detection limit is  $\sim 100 \text{ ng l}^{-1}$ . The most sensitive spectral line for ICP-AES is 290.91 nm. The detection limit is  $\sim 6 \text{ ng l}^{-1}$ . Mass number = 192 is used for ICP-MS detection. The detection limit is  $\sim 0.0005 \text{ ng l}^{-1}$ . Pt<sup>+</sup> (=192), YbO<sup>+</sup> (=192), HfO<sup>+</sup> (=192), and LuO<sup>+</sup> (=192) interfere in Os determination. The detection limit for Os achieved by XRF is of the order of milligram per kilogram for solid samples. NAA is a sensitive technique for Os determination. However, as a common major component in natural samples is iron (Os is a siderophilic element), which would cause a high background in the  $\gamma$ -ray spectrum by the Compton scattering effect, it is very difficult to determine microgram amounts of Os in metallic samples by NAA without separation of Os from iron either by INAA or RNAA. Although RNAA is time consuming compared with INAA, it provides a much higher sensitivity for Os determination below nanogram per gram levels.

## Transmissible Spongiform Encephalopathies

The term transmissible spongiform encephalopathies (TSE) is used broadly to cover a group of neurodegenerative diseases with strikingly similar histopathologies. The diseases of this group known to date in humans are Gerstmann–Sträussler–Scheinker disease, fatal familial insomnia, fatal sporadic insomnia, Kuru, classical Creutzfeld–Jakob disease (CJD), and a new variant of Creutzfeld–Jakob disease (vCJD). Also belonging to the group of TSE is scrapie in sheep and goats as well as bovine spongiform encephalopathy (BSE) in cattle. Transmissible Mink Encephalopathy first appeared in 1947 in mink farms in the USA, the last recorded case of this very rare disease worldwide was reported in the USA in 1985. Furthermore, TSE have been confirmed in eight different species of wild ruminants kept in captivity. An additional animal species affected is the family of cats, not just exotic large cats such as cheetahs, pumas, tiger, and ocelot, but also

domesticated cats, who are susceptible to feline spongiform encephalopathy.

The typical pathological disease profile of TSE is sponge-like (spongiform) changes in brain tissue caused by the formation of microscopically small holes. These particular features as well as additional fundamental characteristics of the demonstrable infectivity of this disease led to the name ‘transmissible spongiform encephalopathy’.

Transmission of a TSE was first achieved by Cuille and Chelle, who managed to infect healthy sheep and goats by intracerebral inoculation of spinal marrow homogenates from sheep suffering from scrapie. Conclusive evidence for the infectious nature of TSE came from long-term inoculation experiment, which succeeded in transmitting CJD and Kuru to chimpanzees.

## Nature and Pathological Action of the TSE Agent

The search for the causative agent of TSE unearthed numerous unusual features that distinguish it significantly from other previously known pathogens. The agent was resistant to formaldehyde and heat

## Transmissible Spongiform Encephalopathies

The term transmissible spongiform encephalopathies (TSE) is used broadly to cover a group of neurodegenerative diseases with strikingly similar histopathologies. The diseases of this group known to date in humans are Gerstmann–Sträussler–Scheinker disease, fatal familial insomnia, fatal sporadic insomnia, Kuru, classical Creutzfeld–Jakob disease (CJD), and a new variant of Creutzfeld–Jakob disease (vCJD). Also belonging to the group of TSE is scrapie in sheep and goats as well as bovine spongiform encephalopathy (BSE) in cattle. Transmissible Mink Encephalopathy first appeared in 1947 in mink farms in the USA, the last recorded case of this very rare disease worldwide was reported in the USA in 1985. Furthermore, TSE have been confirmed in eight different species of wild ruminants kept in captivity. An additional animal species affected is the family of cats, not just exotic large cats such as cheetahs, pumas, tiger, and ocelot, but also

domesticated cats, who are susceptible to feline spongiform encephalopathy.

The typical pathological disease profile of TSE is sponge-like (spongiform) changes in brain tissue caused by the formation of microscopically small holes. These particular features as well as additional fundamental characteristics of the demonstrable infectivity of this disease led to the name ‘transmissible spongiform encephalopathy’.

Transmission of a TSE was first achieved by Cuille and Chelle, who managed to infect healthy sheep and goats by intracerebral inoculation of spinal marrow homogenates from sheep suffering from scrapie. Conclusive evidence for the infectious nature of TSE came from long-term inoculation experiment, which succeeded in transmitting CJD and Kuru to chimpanzees.

## Nature and Pathological Action of the TSE Agent

The search for the causative agent of TSE unearthed numerous unusual features that distinguish it significantly from other previously known pathogens. The agent was resistant to formaldehyde and heat

treatment when attempting to produce a vaccine against scrapie. Investigations showed that the agent is extremely resistant to ultraviolet (UV) and ionizing radiation.

According to the prion hypothesis, the typical TSE damage to nerve tissue is caused by an infectious agent that consists exclusively of a membrane protein altered in its secondary structure. The protein in question is a highly conserved glycoprotein composed of 254 amino acids with a molecular weight of 33–35 kDa. It is found in mono-, di-, and non-glycosylated forms. In its original, physiological form this protein is possibly involved in copper metabolism in the brain and according to recent research also plays a role in the capture of stress-induced oxygen radicals.

One knows that this protein is encoded by a single exon, in humans called the PRNP gene. It is primarily found on the cell surface of neurons, glial cells, and cells of the lymphoreticular system, and it is anchored in these cell membranes via a glucosyl-phosphatidyl-inositol group. The protein is also detected at low concentrations in muscle cells and cells of the immune system.

The trigger for TSE is a structural change in this membrane protein, where certain regions of the protein normally adopting an alpha-helix conformation refold into a beta-sheet structure. This is considered the initiating step for the development of TSE. Its effect on the physical and chemical properties of the protein lead to the extreme resistance to heat, formaldehyde, and UV light referred to above, amongst other properties.

The decisive new property responsible for the damage to nerve tissue is, however, the acquisition of partial resistance to proteases, since the refolded protein cannot be completely degraded. This leads to protein deposits in the form of amyloid plaques in the nerve cells and finally to cell death through apoptosis and other processes. The amyloid plaques are also called scrapie-associated fibrils (SAF). As a result, the brains of damaged individuals show focal and diffuse degeneration and vacuole formation, which are responsible for the typical spongiform appearance of the TSE brain.

A further essential feature of the altered protein is its apparent activity as a crystallization seed: in the proximity of altered proteins, normal proteins are similarly stimulated to refold.

Therefore, the altered protein possesses the essential properties of a disease-causing agent: it has a damaging effect and is able to propagate itself. The unique feature of this pathogenic protein is that in contrast to all previously known infectious agents it is apparently able to propagate itself without the help of nucleic acids. Prusiner named his discovery prion

derived from 'proteinaceous and infectious'. Since then the term prion has come to be used generally for the infectious agents of TSE, even if the agent in question is not one specifically defined.

Subsequently, the physiological, unaltered form of the prion was called PrP<sup>C</sup> for the cellular prion protein and the pathologic, altered form was called PrP<sup>Sc</sup>, derived from the scrapie prion protein.

Prusiner's hypothesis provided a plausible explanation for why TSE does not elicit an immune reaction and why no TSE-associated coding nucleic acids could be found as yet in infectious material. However, it is still not convincingly clarified as to how the conversion from PrP<sup>C</sup> to infectious PrP<sup>Sc</sup> happens without regulating nucleic acids. Although it is possible in cell culture to convert PrP<sup>C</sup> into PrP<sup>Sc</sup> by the addition of PrP<sup>Sc</sup> from infected animals, PrP<sup>Sc</sup> stemming from transgenic organisms are not infectious. Transgenic mice that produce elevated amounts of PrP<sup>Sc</sup> do develop several signs of TSE, but passing on the disease using PrP<sup>Sc</sup> derived in this way has as yet been unsuccessful. This means the conclusive evidence to support the prion hypothesis, in other words the *de novo* synthesis of infectious PrP<sup>Sc</sup>, still remains elusive.

Another hypothesis for the pathological action of the TSE agent is based on the idea that apart from the prion protein another virus-like structure is involved in the development of a TSE disease. This structure comprises a protein coat, a single-stranded DNA layer, and a core of SAFs, and has been called 'scrapie termed nemavirus' (NVP).

As mentioned above, it has not yet been possible to induce an infection by transmission from transgenically produced pure prions. Transmission of TSE is, however, possible with a mixture of single-stranded DNA derived from NVP structures from the brain of scrapie-infected hamsters, and the so-called binding proteins. From this he concluded that the structural changes in PrP<sup>C</sup> essentially require an accessory protein, possibly encoded by the single-stranded DNA of the NVP structure.

The participation of a so-called 'protein X' in the refolding of PrP<sup>C</sup> is also suspected by other authors. Taken together, it seems that although various theories about the pathological action of PrP<sup>Sc</sup> exist, the involvement of this protein in the development of a TSE is, however, generally recognized. How the various forms or phenotypes of TSE are generated can apparently not only be traced back to genetic differences between the affected hosts, but also results from interplay between genetic factors and the action of different pathogen strains.

Individual strains differ in respect to their incubation times as well as with reference to the findings of

histopathological brain examinations. The disruption of nerve cells caused by the accumulation of amyloid plaques leaves different pictures with the individual forms of TSE with respect to the distribution of the vacuoles and degree of tissue damage, producing agent-typical lesion profiles. Individual strains can be identified in experimentally infected laboratory mice by comparing the incubation time and the lesion profile typical for the pathogen. The typical strain characteristics are retained over several generations in experimentally infected mice and are independent of the host. Possibly, the strain-specific information responsible for the differences regarding lesion profile and incubation time is contained within the tertiary structure of the PrP<sup>Sc</sup>.

According to more recent investigations there are also differences with respect to the molecular weight and relative proportion of individual glyco-forms within the PrP<sup>Sc</sup> fraction between individual strains. In addition, it is possible to distinguish between them by using various antibodies.

Differences relating to the parameters mentioned above can be detected between vCJD, a variant of CJD that will be discussed in more detail later, and classical forms of CJD. Various findings concerning these criteria also result from comparisons between scrapie PrP<sup>Sc</sup> and BSE PrP<sup>Sc</sup>. In contrast, the vCJD PrP<sup>Sc</sup> of humans and the BSE PrP<sup>Sc</sup> of cattle, as well as sheep that have been infected with material from BSE cows under experimental conditions, show striking similarities.

## Possible Causes for the Formation of TSE Agents

The formation of PrP<sup>Sc</sup> through alterations in the structure of a normal host protein can have different causes. These are partly determined by differences in the disease progression and in the histopathology of the various TSE forms. In this connection both germ line mutations and somatic mutations are relevant. In addition, an infection can be initiated by implantation of infected tissue. A further source of infection can be oral consumption of the infective agent.

Examples for the different causes of a TSE disease are provided by the various subforms of CJD in humans. CJD was first observed in 1920, and remains one of the best analyzed prion diseases. Classic CJD is divided into three subforms according to the pathogenic mechanism: with 'iatrogenic CJD' patients are infected, for example, through administration of contaminated human growth hormone or transplantation of contaminated dura mater. In addition, the disease can be passed on by contaminated EEG needles in individual cases. In total, more than

267 cases of 'iatrogenic CJD' have been recorded in the last 20 years.

The cause of 'familial CJD' is a germ line mutation in the PRNP gene. To date, 12 mutations are known that seem to be unambiguously associated with familial CJD. The assumption that there is a direct connection between 'familial CJD' and mutations in the PRNP gene was supported experimentally by studies in mice: transgenic mice carrying the mutations mentioned above show several essential aspects of a TSE.

What triggers the appearance of the third form of CJD, 'sporadic CJD', which with one or two cases per million people, per year, worldwide constitutes the major proportion of all TSE in humans, remains unclear. In these cases no connection with mutations in the PRNP gene can be found. Somatic mutations in the PRNP gene have been suggested, although such speculation could not be confirmed experimentally as yet.

A variant of the classical CJD (vCJD) that first appeared in 1993 in the UK differs from the subforms described above in that it preferentially affects younger patients and shows somewhat slower clinical progression. One of the most frequently represented hypotheses for the cause of this disease is infection through oral consumption of products from BSE-affected cattle. Support for this theory comes from the already mentioned similarity between the prions isolated from the brainstem of vCJD patients and BSE animals, which clearly differ from the infective agent and histopathological findings with sporadic and inherited CJD. Lesion profiles that were comparable to the lesion profiles in brains from vCJD patients were found in histopathological analyses of the brain from macaques experimentally infected with BSE.

Additional support for this theory comes from an experiment where transgenic mice that exclusively produce human PrP<sup>C</sup> could be infected with BSE.

The causes for the appearance and spread of BSE are as yet not satisfactorily explained, and extensive research is still required. Experimentally, an infection can be achieved through intracerebral inoculation or oral administration of brain material from infected animals.

The possibility that cows transmit BSE to each other, for example, by infected placenta, amniotic fluid, or contaminated pastureland, could not be confirmed as yet.

Specific mutations that appear in sheep in association with scrapie and the knowledge derived from sheep breeding allowing the selection of scrapie, and BSE-resistant animals, could not be confirmed in cattle as yet.

It is generally assumed that the infective agent reached the cattle population through feeding them animal-meal produced from scrapie-affected sheep where heat treatment was of insufficient duration. Possibly, PrP<sup>Sc</sup> managed to reach the CNS, via peripheral nerves, directly from the digestive tract, or the pathogen first accumulated and proliferated in the lymph organs and later invaded the CNS via the nerve cell network.

In support of transmission via contaminated fodder is the fact that in England at the beginning of the 1980s, in connection with a rationalization measure, the production process for meat and bone-meal was simplified, which subsequently meant dispensing with one procedural step that included steam heat treatment. This step has been shown to reduce the infectivity of PrP<sup>Sc</sup>. The etiology of the BSE epidemic in Great Britain, therefore, indicates that feeding of contaminated animal-meal can be considered the major source of infection. Since the ban on feeding cattle animal-meal, which came into force in the UK in 1989, the number of BSE cases has dropped noticeably.

## Diagnosis of Prion Protein and Transmissible Spongiform Encephalopathies

Basically, as applies to all forms of TSE, a confirmed diagnosis is not possible in a living animal. Although the combination of a range of clinical investigations can justify a suspicion and corroborate it, absolute certainty is only obtained after a histopathological analysis of the CNS, which will be described in more detail later.

The following descriptions concentrate on the field of BSE diagnosis. In order to offer as comprehensive an overview as possible, also concerning theoretically useful methods for BSE diagnosis, additional methods are included that until now have only been applied in human medicine.

### Postmortem Diagnosis

All BSE tests approved so far are either based on histopathological brain analysis or direct detection of PrP<sup>Sc</sup>, which in cattle is still only possible in nerve tissue. Since in the course of the disease prion accumulation appears first and in the highest concentration in the Obex area of the brainstem at the transition between the spinal cord, tissue samples for analysis should strictly be taken from this region.

All practiced methods where diagnosis relies on detection of PrP<sup>Sc</sup> are based on the partial protease resistance of PrP<sup>Sc</sup>. When applying the following test

methods, there is a choice between rapid tests, recommended by the EU Commission for the analysis of larger numbers of samples, and the OIE test methods, which are approved by the International Animal Breeding Authority, and in contrast to the rapid tests used as a screening method, are suited for making a conclusive diagnosis.

**ELISA rapid tests** As a screening method for analyzing larger sample numbers, two out of three procedures evaluated by the EU Commission as sufficiently sensitive are approved. The method preferred by most laboratories is an enzyme-linked immunosorbent assay (ELISA) procedure where homogenized tissue is subjected to proteinase K hydrolysis. PrP<sup>C</sup> is completely digested, while with PrP<sup>Sc</sup> only the first 62–80 amino acids are cleaved off. The remaining PrP<sup>Sc</sup> is fixed on an ELISA plate using antibody already bound to the plate. Binding of a further labeled antibody to the fixed PrP<sup>Sc</sup> leads to a color change that allows detection of PrP<sup>Sc</sup>.

A further ELISA works not through using a color change, but by photometric measurement of a chemiluminescence signal. This achieves higher sensitivity.

**Western blot rapid test** In contrast to the two ELISA rapid tests, a third rapid test procedure based on the Western blot principle offers the advantage that it not only detects the presence of PrP<sup>Sc</sup> but at the same time determines the molecular weight of the protein. This provides a control parameter for assessing the completeness of the proteinase K digestion. The disadvantage of this test is the lack of defined endpoint. The isolation of PrP<sup>Sc</sup> is achieved by separating the protein fraction of the homogenized brainstem preparation using SDS polyacrylamide gel electrophoresis (Figure 1).

**OIE Western blot** With the approved OIE Western blot test the isolation of PrP<sup>Sc</sup> is achieved in a different way from the Western blot rapid test, by using several successive ultracentrifugation steps during which the PrP<sup>Sc</sup>, which tends to form fibrillar structures, accumulates in a pellet and is thus separated from normal PrP<sup>C</sup>. This step, although laborious, considerably increases the test sensitivity, and is followed by a proteinase K digest as described above in the Western blot rapid test and subsequent detection by Western blotting. Due to the time consuming preparation of the material to be analyzed, this test takes several days and is not suited for use as a screening test.

**Immunohistochemical analysis** A further procedure approved by the International Epidemic Authority is

**Figure 1** Autoradiogramme of Western blot rapid test. Different dilutions (1:1 to 1:1024) of a brain homogenate from the Obex region of a BSE-infected cow were digested with proteinase K together with positive (+) and negative (-) controls. After digestion, the samples were loaded on a SDS-PAGE and separated. After blotting onto a nylon membrane, the filter was hybridized with a Prp-specific antibody and PrP<sup>Sc</sup> was detected by a chemiluminescence detection method after exposure to an X-ray film. PrP<sup>Sc</sup>-ug, unglycosylated PrP<sup>Sc</sup>; PrP<sup>Sc</sup>-g1, single glycosylated PrP<sup>Sc</sup>; PrP<sup>Sc</sup>-g2, double glycosylated PrP<sup>Sc</sup>.

the immunohistochemical analysis of brain tissue preparations. Tissue blocks 2 µm thick are hydrolytically autoclaved. Following this preparation accumulation of PrP<sup>Sc</sup> in nerve cells can be visualized using a PrP<sup>Sc</sup>-specific antibody and subsequent staining. This method is highly sensitive and also provides rough, ordered anatomical information.

**Histoblot** A further test procedure is the histoblot. Here, blocks of tissue 2 mm thick are transferred to nitrocellulose membranes, lysed, and subjected to proteinase K digestion. Following proteinase K digestion over 8 h at 55°C, protein is subsequently fixed to the membrane. After blocking the membrane with a protein solution the membrane is treated first with a PrP<sup>Sc</sup>-specific antibody and then a second antibody directed against the PrP<sup>Sc</sup>-specific antibody. This second antibody is stained with Formazan, meaning the immunoreaction can be visualized under the microscope. The histoblot permits sensitive protein detection and provides detailed anatomical information. The disadvantage is that only freshly frozen material can be used. Samples stored in formaldehyde solution that are perfectly suitable for carrying out other procedures cannot be used, since such material is too soft to dissect into sufficiently small tissue blocks for transferring to the nitrocellulose membrane.

**PET-blot** A very sensitive and new procedure that overcomes such problems is the so-called paraffin embedded tissue blot (PET-blot). By covering

**Figure 2** PET-blot analysis of a BSE-infected brain. Deposition of PrpSc in the brain was detected by the PET-blot technique. PET-blot provided with courtesy of Dr W. Schulz-Schaeffer.

samples stored in formaldehyde solution with paraffin, tissue blocks of 5–7 µm in size are cut that are small enough to be fixed on a nitrocellulose membrane. After the paraffin is released from the membrane-bound proteins, proteinase K digestion and subsequent immunodetection is carried out as with the histoblot. Even in cases where the immunohistochemical analysis gave ambiguous results, the PET-blot can clearly detect PrP<sup>Sc</sup> and is more sensitive than conventional Western blot and histoblot procedures (Figure 2).

**Histopathological analysis** Similarly, histopathological analysis is suitable merely to confirm and not to refute a suspected case of BSE, and detects vacuolization in certain areas of the brain. The majority of TSE cases are accompanied by focal or diffuse degeneration of the gray matter in the entire CNS, above all in the cerebellum, as well as the formation of vacuoles. As a result, damage to the nerve cells in addition to proliferation and enlargement of astrocytes is observed. During damage to the nerve tissue microscopically small holes are formed that are responsible for the sponge-like appearance of the brain in TSE.

**Electron microscope analysis** Electron microscope visualization of prion accumulation, also known as scrapie-associated fibrils or amyloid plaques, which are isolated by ultracentrifugation as described above, is also approved as a diagnosis procedure. This procedure was frequently used at the beginning of the BSE epidemic in England, although since then it has proved to be less reliable than the methods described above.

**Approaches to a Premortal Diagnosis**

In this section, clinical BSE diagnostic techniques will be discussed in detail. Subsequently, to complete the picture further methods that play more of a secondary role in BSE diagnosis will be covered briefly, since in part they have applications exclusively in human medicine or are still under development.

**Clinical analysis** BSE-infected cows normally show a distinct pattern of clinical signs, including three complexes, i.e., ‘behavior’, ‘sensitivity’, and ‘movement’.

As suspect behavioral disturbances changes in anxiety and character are typical. Most frequent are disturbed defensive reactions such as being easily startled (in 66% of animals), anxiety (in 66% of animals), and nervousness or restlessness (in 64% of animals). Concerning aggressive behavior, increased readiness to repulse approaches was apparent in 36% of the animals, maliciousness and lashing out in 20% of animals. Fear of narrow passages and small obstructions was more seldom.

To assess sensitivity, reactions to manipulation of the neck and head as well as to noises and light were tested and the so-called broom test was carried out where the severity of lashing out upon touching the shackles with a broom was observed. Typical observations of arousal during the sensitivity test were defensive movements or more sedate arousal

reactions such as salivation, snorting, nervous ear twitching, licking the rim of the mouth, and quivering muscles. Furthermore, repeated or even a progressively more severe shock reaction upon repeating the same light or noise stimulation was interpreted as an indication of BSE. Over-sensitivity to tactile stimulation was apparent in 98% of animals, 84% reacted hypersensitively to noise, but light sensitivity was observed in only 45% of animals.

As BSE-typical features for the animals’ movement, hesitation and anxiety are observed when crossing the septic tank or passing through the stall door, disturbed balance and ataxia of fore and hind legs and hypermetria. About 92% of the animals showed ataxia, whereby a generalized ataxia appeared twice as frequently as one restricted to the hind legs. Less frequent was problems with standing up, lying down, and falling over. Often the disturbances in movement were only weakly manifest.

Animals showing at least two of the three signs of complexes of behavior, sensitivity, and movement disturbances, in most cases in fact all three, are BSE positive. Therefore, precise examination of all three complexes is indispensable, since some signs may only be weakly manifest particularly in the early stages.

A clinical calibration of BSE-investigated animals into four diagnostic categories is based on these observations (**Table 1**).

Often milk production and underfeeding can be observed. The cows’ appetite is graded as normal, similarly the frequency of rumen contractions. From observations of reduced strength of contractions and the rumen content, it can be concluded that the poor nutritional state of the animals, despite the normal desire to feed, could be traced back to lower ingestion of food.

A further clinical finding considered as being of possible diagnostic interest is a bradycardia. Here,

**Table 1** Clinical BSE diagnosis

Group	Clinical diagnosis	Clinical findings (various possibilities)
I	BSE	All typical findings present (disturbed behavior, movement and sensitivity), or Two major signs clearly manifest (e.g., easily startled and atactic or nervous and sensitive to noise)
II	No BSE	No signs typical for BSE, or One single finding mildly positive (e.g., mildly startled by noise or mild sensitivity to manipulation of the neck), or Disturbed movement without disturbed behavior or sensitivity
III	Suspected BSE	Strongly pronounced behavior disturbances (nervous, anxious, easily startled), or Strongly pronounced disturbed sensitivity (over sensitive to manipulation, noise, light)
IV	BSE not excluded	Two main signs mildly pronounced (e.g., relatively easily startled and mildly sensitive to light), or One individual finding clearly positive (e.g., startled by noise), other major signs clearly negative

this refers to a significant slowing down of the pulse rate. This observation seems in contradiction to the nervous and anxious state of the animals. A possible explanation can be attributed to the pathological-anatomical changes in the vagus nerve, which could lead to increased vagal tone. Increased intracranial pressure is one of the possible causes for a bradycardia. It cannot be excluded that ECG findings after further detailed investigations could have a diagnostic significance.

The normal clinical blood chemistry and hematological values routinely determined in the laboratory, as well as the urine results, gave no indication of BSE. In contrast, the analysis of cerebrospinal (CS) fluid could be useful, since this can be a means to exclude other CNS diseases such as encephalitis, which in contrast to BSE are accompanied by inflammatory changes in the CS fluid. However, more detailed use of CS fluid data determined within the framework of routine clinical analyses for the diagnosis of BSE can be excluded. This is also confirmed in human medicine investigations.

**Blood analysis** To directly detect prion proteins in blood one could take advantage of the specific binding of PrP<sup>Sc</sup> to plasminogen, as soon as the specificity of this binding is clearly defined.

A further approach to diagnosing TSE is based on the detection of cellular nucleic acids in serum (CNAPS). Production of such nucleic acids is apparently very specific, for example, as a result of malignant diseases, autoimmune diseases, and infectious diseases and opens up the possibility of diagnosing such diseases through the detection of these nucleic acids. Possibly, this reaction to diseases is part of an older immune system. Investigations with diverse serum material from cattle provided optimistic results. The CNAPS are present in the liquid fraction of blood samples from both healthy and diseased cattle. The CNAPS were found in the blood fraction that contains primarily microvesicles. CNAPS profiles have been shown to differ in humans with multiple myeloma and mysterious neurologic syndromes such as Gulf War syndrome and chronic fatigue syndrome.

**Electroencephalogram (EEG)** In human medicine electroencephalographic findings are brought in as a further diagnostic aid. The so-called 'periodic sharp wave complexes' appear with ~60–70% of patients with sporadic CJD.

**Nuclear magnetic resonance spectroscopy** Also, nuclear magnetic resonance spectroscopy or nuclear spin tomography (MRI, magnetic resonance imaging),

which depicts body structures through imaging the distribution of free-moving hydrogen atom, has some importance as diagnostic tool. Amongst other things, this can visualize atrophy in the brain, although atrophy in several brain regions is not one of the major signs for confirming a suspected CJD. In various investigations, abnormal symmetrical elevated signals in the caudate nucleus and putamen were found in up to 67% of the suspected patients analyzed. Above all, MRI findings played a role in distinguishing between vCJD and sporadic CJD. Up to 80% of vCJD cases showed hyperintensities in the posterior thalamus that clearly exceeded the elevated signals in the caudate nucleus and putamen. This provides a possibility to clinically differentiate between vCJD and sporadic CJD.

**Positron emission tomography** Furthermore, positron emission tomography delivered useful results in a first analysis with a small number of patients. This method involves injecting patients with labeled ions, for example, oxygen, carbon, fluoride, or glucose. A reaction takes place, releasing radiation, when these positively charged particles meet a negatively charged counterpart in the body. This emission can be measured and localized, thus making it possible to build up a picture of the distribution of individual molecules in particular regions of the body. All the patients investigated showed reduced glucose metabolism in the brain. The distribution of the area of reduced glucose metabolism differed significantly from the typical pictures obtained with other brain diseases included as comparisons, such as Alzheimer's, Parkinson's, frontal temporal dementia, Lewy body dementia, Wilson's disease, Huntington's disease, and dementia due to blood vessel damage.

**Bioassay systems** Particularly in animal studies, an increasingly applied option for detecting the presence of a TSE infection is the inoculation of mice or hamsters with infectious material taken by biopsy from the brain of the animal or human under investigation. Against its use in the clinic is the highly variable sensitivity of this bioassay system, the not insignificant risk of damage following the brain biopsy for the patient under examination, and the disadvantage that due to the incubation time the results are only available much later.

## Cerebrospinal Fluid Analyses

### Direct Detection of Prions in CS Fluids

**Detecting infectivity in CS fluids** Standard diagnostic analyses of cerebrospinal fluids from cattle or even

from people have resulted in no notable findings. Evidence was provided for the infectivity of cerebrospinal fluids when infecting primates by inoculation with undiluted cerebrospinal fluid from CJD patients. Considering the high receptivity of primates for CJD, this transmission rate of only 15% is perhaps low, but can be rated as indirect evidence that CS fluids contain PrP<sup>Sc</sup>. In an Internet publication from the Paul Ehrlich Institute, where bovine tissue, secretions, and excretions are divided into four categories according to their prion content, CS fluids are allocated to the category – high infective agent content – and thus lie between the categories ‘very high infective agent content’ and ‘moderate infective agent content’.

**The SIFT method** Direct detection of PrP<sup>Sc</sup> in CS fluids is now possible. Using the method SIFT (scanning for intensely fluorescent targets), the lowest molecular concentration that could be detected was less than a femtomole. This method represents a further development of classical fluorescence spectroscopy. It includes an immunoreaction of the molecule to be detected with specific antibodies that are labeled with a fluorescent compound. A light beam causes these marker compounds to fluoresce at a characteristic wavelength. Light of the expected wavelength is selectively conducted by an emission filter or monochromator to a detector, where it is converted into electrical energy and transferred via an amplifier to a monitoring device.

The intensity of the fluorescent signal from the marker compound is weak, but increases 50-fold when it is bound to an antibody. This means fluorescent signals from possible free macromolecules in the sample under investigation can be distinguished from those arising from the substance being sought.

In classical fluorescence spectroscopy, in contrast to the SIFT method, the entire sample is exposed to the light beam and the fluorescence intensity, which results from the sum of the signals received from the preparation, is measured within a particular time-frame. Here, scattered and reflected light photons create the so-called background noise, which tends to drown out fluorescence signals from the small amounts of molecules to be detected. Therefore, with this method only amounts above the nanomolar level can be detected.

In order to cut down interfering effects such as background noise, only a small proportion of the volume is light-activated in the SIFT method, which then emits correspondingly little scattered light. If the labeled substance to be detected enters this focus, it emits several thousand fluorescence light photons within a few milliseconds in the form of sequential

rapid-fire flashes of fluorescence. These are detected using autocorrelation. Moreover, the fluorescence intensities measured in two directly sequential time intervals are multiplied together. If the emitting particle in the focus is the sought molecule, then the expected signal in the two sequential time intervals is measurable and the product of both measured intensities does not equal zero. A possible interference signal of background noise, in contrast, is expected to be in the form of a few flashes that are only visible for the duration of the measuring interval. The product of the two fluorescence intensities in the two sequential time intervals is in this case equal to zero. In this way, the principle of autocorrelation permits separation of specific signals from unspecific signals. Unspecific signals mostly arise from free, labeled antibodies or those bound to PrP<sup>C</sup> arriving in the measuring focus, which in contrast to those bound to PrP<sup>Sc</sup> are single and not present in the form of agglomerates.

In order to increase the specificity of the measurements, the developers of the SIFT method target the molecule to be detected with two antibodies instead of one. The antibodies, one of which is ‘stamped’ with a green fluorescence marker, the other with a red fluorescence marker, each bind specifically to two different sites on the molecule. The measuring device is equipped with two light-sensitive detectors, one for green and one for red. A specific reaction means a simultaneous measurement of both green and red fluorescence signals.

**Application of the SIFT method in clinical diagnosis** Concerning its application in clinical diagnosis the described procedure still shows major deficits. Investigations with a total of 24 CS fluid samples from confirmed CJD patients and 13 control samples from definite non-CJD patients resulted in no positive signal in the control samples. Therefore, diagnostic specificity was 100%. However, with a sensitivity of ~20%, where PrP<sup>Sc</sup> could only be detected in five out of 24 fluid samples, this method is far from being suited for use in clinical diagnosis. It remains to be established whether all CJD patients really have measurable amounts of PrP<sup>Sc</sup> in their CS fluid. There is still justifiable hope that this method, through appropriate optimization, can be developed in the future into a specific diagnostic tool.

## Surrogate Markers in CS Fluid

Due to the lack of available procedures for reliable, direct detection of prions in CS fluids, suitable surrogate markers for TSE were sought; in other

words, molecules that are as specifically as possible found in association with TSE fluids.

What was found in CS fluids of CJD patients was increased levels of the brain proteins: neuron-specific endolase (NSE), Tau protein, S-100b, G<sub>0</sub>-protein, and brain-specific creatine kinase, amongst others. All these proteins are observed to increase in concentration in CS fluids as the CJD condition progresses. In the final stage of the disease their concentrations decrease again. In addition, in CJD patients, as with Alzheimer's patients, a reduced concentration of A $\beta$ -amyloid in CS fluids was found.

Of particular significance as surrogate marker proteins are a group of brain proteins known as 14-3-3, which currently play an important role in the diagnosis of familial and sporadic CJD. Among other things, these proteins are involved in diverse metabolic processes in nerve cells. 14-3-3 proteins appear in the cerebrospinal fluid when acute nerve cell loss or acute brain disruption occurs, as with TSE, but also with strokes and several other diseases (herpes simplex encephalitis, multi-infarct dementia, acute infarct, subarachnoid hemorrhage (bleeding in cerebrospinal space), viral encephalitis).

In the literature, the parameters of specificity and sensitivity are used in particular to compare various surrogate marker tests and diagnostic procedures, as well as to provide a reference point for evaluating the predictive accuracy of individual tests with respect to a CJD diagnosis.

Specificity represents the percentage of marker-negative patients in the group of definitely not CJD-affected patients. This means it is a measure of the certainty with which the marker test recognizes a CJD-negative patient as being such.

Sensitivity indicates the proportion of marker-positive patients in the group of definitely or probably CJD-affected patients. Thus, sensitivity provides a reference point for the certainty that definite or probable CJD-positive patients can be identified within a suspect group using the marker test. Patients that are graded as probably CJD-positive demonstrate advanced dementia with a duration of less than 2 years in connection with at least two of the clinical characteristics of myoclonus, visual or cerebellar signs, pyramidal or extrapyramidal signs, as well as akinetic changes, and show in EEG 'periodic sharp wave complexes'.

Table 2 shows the sensitivity and specificity of selected surrogate marker test procedures in comparison with other diagnostic techniques in sporadic CJD. Sensitivity and specificity refer to a given selection of patients whose neurological and psychiatric condition fits in the differential diagnosis context.

**Table 2** Sensitivity and specificity of diagnostic techniques in sporadic CJD

Marker	n	Sensitivity (%)	Specificity <sup>a</sup> (%)
<i>Cerebrospinal fluid</i>			
14-3-3	1136	95	93
NSE > 35 ng ml <sup>-1</sup>	1276	81	92
S100 > 4.2 ng ml <sup>-1</sup>	135	84	91
Tau > 1400 pg ml <sup>-1</sup>	290	93	91
PrP <sup>Sc</sup>	34	20	100
MRI	208	63	92
EEG	805	66	74

<sup>a</sup>In neurological/psychiatric conditions, which are relevant in the differential diagnosis.

From Table 2 it is clear that the 14-3-3 test, in comparison to other diagnostic procedures, shows a particularly high specificity and sensitivity. Also, relatively high sensitivity and high specificity are reported for detecting Tau protein.

In a comparison of the Tau protein test with the 14-3-3 test with a group of 297 patients the Tau protein test performed just as well in the parameters of sensitivity and specificity as the 14-3-3 test. The authors concede, however, that the 14-3-3 test in these investigations gave poorer values than with earlier analyses carried out by them. They attribute the cause to the fact that in the earlier investigations the group of definite and probable CJD cases served as the basis for evaluating specificity and sensitivity, whereas the evaluation parameters in the investigation described here were calculated based merely on definite cases.

### Various Detection Procedures for 14-3-3 Proteins

**14-3-3 detection using two-dimensional gel electrophoresis** Using two-dimensional gel electrophoresis the proteins p130 and p131 were detected, which later turned out to belong to the group of 14-3-3 proteins, in CS fluids of 21 CJD patients. In an investigation with 100 healthy volunteers, 420 patients with other nervous disorders and 21 CJD patients, a sensitivity of 100% and a specificity of 91% was obtained.

The diagnostic usefulness of a combination of Harrington's p130/131 detection system with measurement of the NSE concentration in CS fluids was tested. Harrington's p130/131 detection gave a sensitivity of 84% for sporadic CJD and 81% for familial CJD. The specificity in these investigations was 100%. The p130/131 proteins were detectable in 47 out of 58 definite CJD cases, in 37 out of 46 probable cases, and in 23 out of 34 possible cases. In

44 definite cases of other diseases p130/131 could not be detected. Therefore, the p130/131 test is recommended as a backup diagnosis in CJD cases diagnosed clinically as possible or probable, and which show an NSE concentration of over 20 ng ml<sup>-1</sup> in CS fluids.

**14-3-3 Western blot immunoassay (immunostaining)** The p130/131 proteins were also detected in normal brain tissue and identified with the help of partial sequence analysis as the already known 14-3-3 brain proteins. This information made it possible to develop a new method for detecting the proteins using immunoassays.

This method involves electrophoretically separating the protein fraction of CS fluid and subsequently transferring these proteins to a nitrocellulose membrane according to Western blot procedures. After saturating the free binding sites on the membrane with a Tris-buffered salt solution, the membrane is treated with the 14-3-3-specific antibody ‘anti-14-3-3 $\beta$  polyclonal rabbit antibody’. A second antibody binds this antibody, the ‘alkaline phosphatase-conjugated anti-rabbit IgG antibody’. Detection is achieved by a colorimetric reaction.

With this new method a sensitivity of 96% was attained: 14-3-3 proteins were detected in CS fluids from 68 out of 71 definite CJD cases. Out of 137 samples from patients with other nervous disorders, 22 were 14-3-3 positive. This gives a relatively low specificity of 83.9%. If within the group of patients with other diseases one only takes into account the proportion that show dementia and suffer no stroke within a month of lumbar puncture, specificity increases to 99%: of the 91 patients who fulfilled these criteria, 14-3-3 proteins were detected in only one. This patient suffered from Alzheimer’s. Due to these false-positive results the authors recommend caution

in interpreting the 14-3-3 test results and stress that importance should only be attached to the results of these tests in connection with clinical investigations.

The new method was compared with the detection method of Harrington using two-dimensional gel electrophoresis (Table 3). In this experiment based on 50 samples the results of both tests matched except for the number of positive samples within the category ‘clinically certain’ CJD cases. Within this category 14-3-3 proteins could be detected using an immunoassay in all patients, whereas using two-dimensional electrophoresis detection was successful in only 13 patients. Therefore, the authors attribute a slightly higher sensitivity to the immunoassay than to the two-dimensional electrophoresis.

An immunoassay investigation detected 14-3-3 proteins in CS fluids from every one of the 20 patients investigated, who were definitely suffering from sporadic CJD, whereas the results of CS fluid analysis of 20 patients with dementia due to other diseases were negative for 14-3-3. The authors, therefore, rate the immunoassay as highly sensitive and specific for the diagnosis of CJD.

The high sensitivity and specificity of the 14-3-3 immunoassay was also confirmed by other investigations. In a study with 484 patients, the positive predictive value of the 14-3-3 immunoassay reached 94.7% and the negative predictive value 92.4%. The sensitivity within the group of definite CJD patients was 95.4%, within the group of probable CJD patients, 92.8%. Altogether, the sensitivity was 94% and the specificity 93.3%.

The appearance of 14-3-3 proteins in CS fluids was also investigated in 80 patients with paraneoplastic nerve defects (PND), in order to test whether a false CJD diagnosis might possibly be reached due to a positive 14-3-3 test result with these patients. As a positive control the team included 53 CS fluid

**Table 3** Comparison of two-dimensional electrophoresis for protein 130 and 131 with the 14-3-3 immunoassay

Diagnosis	Total number of samples	Positive samples	
		Two-dimensional electrophoresis	14-3-3 immunoassay
CJD			
Pathologically confirmed	5	5	5
Clinically certain <sup>a</sup>	10	8	10
Total	15	13	15
Other diseases			
Dementia	18	0	0
Other neurological diseases	13	1	1
Total	31	1	1
Healthy control samples	4	0	0

<sup>a</sup>Clinically certain is defined as rapid advancing dementia with myoclonus and characteristic encephalographic results.

samples from CJD patients; as a negative control, CS fluid samples from CJD-negative patients with various nervous defects were similarly subjected to the 14-3-3 test. Among the samples from the 80 PND patients, 12.5% showed a positive reaction for 14-3-3, while 14-3-3 proteins were detected in CS fluids from 48 out of the 53 CJD-positive patients (i.e., 90.6%). In the group of 55 CJD-negative patients, six were 14-3-3 positive.

An investigation with 805 patients resulted in a sensitivity for the 14-3-3 immunoassay of 94% and a specificity of 84%.

In general, the 14-3-3 immunoassay can be considered as a sensitive and specific parameter in the diagnosis of sporadic CJD. The 14-3-3 test is not suited for diagnosis of vCJD, since the sensitivity with these patients lies at just over 50%.

**14-3-3 Western blot immunoassay (chemiluminescence)** Bernheimer published the results of their 14-3-3 test on 20 suspected CJD patients, of which three proved to be actually CJD positive and five were assessed as probable cases, as well as 18 comparable cases with other diseases. The detection method was the only way the test differed from the procedure of Hsich described above: detection of the 14-3-3 proteins was not achieved using immunostaining, but according to the chemiluminescence procedure.

The 14-3-3 test results were distributed similarly to the investigations described above, even if the authors did reject direct comparison with previous studies of sensitivity and specificity on the grounds of low sample numbers. The three CJD-positive patients showed a positive 14-3-3 reaction. Amongst the five probable CJD cases, one was positive for 14-3-3. Two patients assessed as possible CJD cases reacted negatively for 14-3-3, and from the remaining 10 not diagnosed, suspected CJD patients, eight were 14-3-3 positive. Among the 18 control patients there were six with positive 14-3-3 test results. In investigations of CS fluids from vCJD patients, a combination of the 14-3-3 test with Tau protein detection improved the negative and positive predictive values of both tests. The positive predictive value for the 14-3-3 test was 86%, the negative predictive value 63%. The Tau protein test attained a positive predictive value of 93% and a negative predictive value of 81%. Combination of the results from both tests, however, resulted in a positive predictive value of 91% and a negative predictive value of 84%.

**14-3-3 detection using ELISA** On the basis of the immunoassay, an ELISA was developed that, in

contrast to the immunoassays described above, allowed not only qualitative but also quantitative detection of the molecule under investigation.

Here, the monoclonal 'capture anti-14-3-3 antibody' added to the wells of a so-called microtiter plate made up of a number of regularly assembled wells per plate, and binds tightly to the bottom of these wells. The samples to be investigated and 14-3-3 standards with known concentrations of 14-3-3 proteins are pipetted in the wells and after a reaction time during which the 14-3-3 proteins bind to the 'capture antibody' on the bottom of the microplate, they are rinsed with washing solution. A protein-containing solution added subsequently to the wells serves to block remaining unbound 'capture antibody'. Following more washing steps, two detection antibodies are added in sequence to the wells. These are the rabbit anti-14-3-3 $\beta$  polyclonal antibody, which binds specifically to the 14-3-3 protein, and the peroxidase-labeled goat anti-rabbit IgG antibody that binds to the first antibody. After the immunoreaction TMB is added as substrate for the colorimetric reaction. The enzymatic reaction that takes place leads to a certain degree of staining that depends on the amount of 14-3-3 protein bound in the well. Quantification is achieved by comparing the absorption values of the different samples with the absorption values of the 14-3-3 standards.

The lowest amount of 14-3-3 protein detected using the ELISA was a concentration of 2.1 ng ml<sup>-1</sup>. Comparison of the new ELISA method with the Western blot immunoassay using samples from 63 definite or probable CJD patients and 84 samples from patients with other neurological defects resulted in a sensitivity of 92.7% for the ELISA relating to the definite CJD patients; with reference to the definite and probable CJD patients, sensitivity was 88.9%. In contrast, the sensitivity of the Western blot immunoassay within the group of definite CJD patients was 95.1%, and in the group of definite and probable CJD patients it was 93.7%. The specificity for both tests was 97.6%.

At the same time a 14-3-3 protein ELISA was developed, which achieved a relative quantification of the 14-3-3-protein concentration in CS fluid from CJD and non-CJD patients. To determine the sensitivity of the ELISA, the 14-3-3 content in extracts from cattle was also measured in parallel using ELISA and immunoblots. For the ELISA the lowest amount of 14-3-3 protein detectable was a concentration of 0.5 ng ml<sup>-1</sup> and for the Western blot immunoassay a concentration of 4 ng ml<sup>-1</sup>. This test should make it possible, through its high sensitivity and quantification of the 14-3-3 concentration in investigated material, to distinguish between various

forms of CJD, which have different levels of 14-3-3 concentrations in CS fluids.

Comparison of the ELISA with a Western blot immunoassay revealed a higher sensitivity of 95% for the ELISA compared to 93% for the immunoassay. With reference to specificity, however, the Western blot immunoassay came off better, with 100%, than the ELISA with merely 92%.

## Introduction

Process analysis is the application of analytical science to the monitoring and control of industrial processes. The data obtained from process analysis allow the control and optimization of industrial

forms of CJD, which have different levels of 14-3-3 concentrations in CS fluids.

Comparison of the ELISA with a Western blot immunoassay revealed a higher sensitivity of 95% for the ELISA compared to 93% for the immunoassay. With reference to specificity, however, the Western blot immunoassay came off better, with 100%, than the ELISA with merely 92%.

## Introduction

Process analysis is the application of analytical science to the monitoring and control of industrial processes. The data obtained from process analysis allow the control and optimization of industrial

processes by providing information from which the chemical and/or physical composition of the process stream can be obtained.

Process analytical chemistry (PAC) techniques have been grouped into the following categories.

- **Offline:** A sample is removed from a process stream or reactor and transported to a centralized laboratory where it is analyzed by skilled analysts on sophisticated equipment. This has the advantage that expensive instrumentation can be shared for the analysis of different types of samples. However, these samples can take hours or even days to be analyzed and this can cause a delay to production. There can also be confusion caused by differing opinions on the priority of a sample and the ownership of the data produced by the analysis.
- **At-line:** A dedicated analytical instrument is placed next to or close to the process stream. This allows faster sample analysis with a simpler, less expensive instrument and gives process operators closer control of the analysis. An at-line instrument must be robust enough to cope with conditions on the chemical plant, e.g., temperature, solvent atmosphere, and vibrations.
- **Online:** A sample is automatically removed from the process, conditioned, and then passed to the process analyzer for measurement. Online analysis can be continuous, where the sample flows continually through the analyzer, or intermittent, where aliquots of the sample are injected into the instrument at various time intervals. A dedicated instrument is utilized for the analysis of the process stream. Included under the umbrella of online techniques are inline and noninvasive techniques.
- **Inline:** Analysis is carried out by a probe that is placed directly inside the process stream. This removes the need for a separate side arm to transport the sample for analysis to the instrument.
- **Noninvasive:** This is seen as being the main aim of any process analysis technique. With noninvasive techniques, there is no physical contact between the analyzer and the sample. This removes any problems with sampling that may be encountered, e.g., probe fouling.

The advantages and disadvantages of the different categories of PAC are summarized in **Table 1**.

The instrumentation used in at-line and online analysis differs from laboratory instrumentation in that it is rugged and dedicated to a particular task, i.e., continually monitoring the same process stream, whereas laboratory-based analytical instruments are usually used to determine many analytes. Process analyzers are usually installed in safe analyzer houses that are kept at a constant temperature and pressure and have air continually passed through them to

**Table 1** Advantages and disadvantages of the different categories of PAC techniques

	<i>Advantages</i>	<i>Disadvantages</i>
Offline	Expert analysts available Flexible operation Controlled environment Sophisticated instrumentation Low unit cost per test	Can be slow Lack of ownership of data Conflicts of priorities
At-line	Dedicated instrument Faster sampling process  Simpler instrumentation Ownership of data by production personnel Control of priorities	Low equipment utilization Equipment needs to be robust to cope with production environment Data can be of poor quality
Online	Fast  Automatic feedback possible Dedicated analyzer  Can potentially be noninvasive	Minimum downtime required Long/expensive method development 24 h troubleshooting/maintenance resource required Electrical classification required Data can be of poor quality

remove any harmful vapors from the process that may be leaking into the safe house.

Traditionally, process analysis is carried out by manually removing a sample from a process, followed by offline analysis in a centralized laboratory. The samples are analyzed by qualified technicians using state-of-the-art instrumentation. Typically, it can take a few hours or even a few days for the results to be obtained and reported back to production personnel. The results from the analysis are then used retrospectively to determine the yield obtained, whether the material needs to be reworked or discarded, or to assess material going on to the next stage of a multistage batch process. While the results are awaited from the analytical laboratory, the process may be sitting idle when reactors could possibly be getting prepared for the next process. In a multistage batch synthesis, the next stage of the process cannot be started until the analytical results are obtained from the laboratory. In both cases the cycle time of the process is increased. The advantages obtained from using at-line or online process analyses are increased efficiency of the plant, increased safety, and the reduction of pollution. The efficiency of the plant is increased as there is no down time while results are awaited from a centralized analytical laboratory. Real-time results from an online process analyzer can be used in a feedback loop to maintain the conditions of a reaction. This helps to lower the 'quality cost' of production – the loss experienced

when a batch of material fails to meet the required specification and so has to be reworked, sold as lower standard material, or discarded altogether.

Figure 1 shows the steps involved in offline and online process analysis and it can be seen that online analysis takes less time to produce the data required for process control.

Reports have shown that when online analysis was used to control various parameters of a gas liquefaction plant, large savings in energy usage and therefore cost can be made. An example of process analysis increasing safety is in the production of ethylene. The presence of oxygen in the process can lead to the reaction becoming out of control which jeopardizes lives and plant equipment, so it is prudent to have the oxygen content of the reaction mixtures continuously monitored online and in real-time. Online analysis helps to minimize the waste produced by a production plant because as process efficiency is improved, fewer resources are lost to effluent streams. The concentration of any pollutants can also be monitored directly with a process analyzer to ensure that the least possible amount of unwanted material is produced. Using online process analysis is a much preferred method of pollution control as it involves the 'prevention' of pollution rather than the 'cure' of treating waste streams before they are released into the environment. Online analysis requires long and expensive method development. Expertise from many individuals is required if a technique is to be implemented successfully, e.g., analytical chemists, process engineers, process research and development chemists, chemometricians, and the

production manager. Round the clock resources for maintenance and troubleshooting are required, as the analyzer would be expected to work continually with minimum down time. If an analyzer is to be placed directly into the plant, it may be necessary for electrical classification tests to be carried out to permit the analyzer to be situated in the plant atmosphere, especially if it contains a significant concentration of solvent. This may require the analyzer to be kept in a specially designed analyzer house, where the atmosphere around the instrument can be controlled.

The move toward online analysis has been caused by the increased international competitiveness between companies in the chemical industry. In an increasingly consumer driven market, chemical manufacturers must supply their customers with products of a consistently high quality, and be able to supply these products when required by the customer. The increased control obtained by using online analysis allows the quality of materials to be maintained, and reduces delays in the delivery of products by reducing the number of batches that require to be reworked or discarded. The adoption of online analysis by the chemical industry has been aided by developments in microcomputer technology and analytical instrumentation, allowing data and hence information to be generated almost instantaneously.

## Techniques Currently Used in Process Analytical Control

Surveying the literature, it can be observed that most of the major techniques used in analytical chemistry are already in use as online process analyzers.

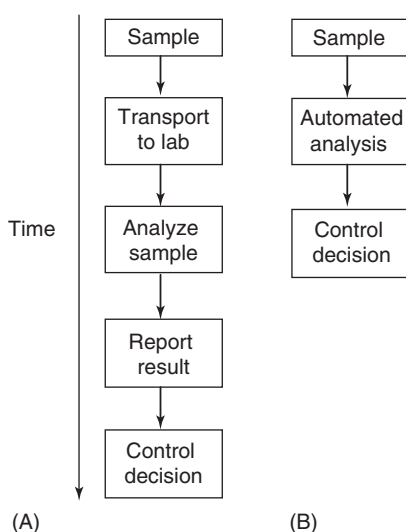

### Chromatography

Gas chromatography has become the one of the most widely used techniques in PAC for the analysis of volatiles. The applications in which it has been used include the determination of octane number in fuels using *n*-alkanes as reference peaks and to control the hydrogen/nitrogen ratio in ammonia production. A disadvantage of process gas chromatography is that there is a delay as the sample passes through the column before the results are known.

At the moment, process liquid chromatography is still under development to improve the reliability and ruggedness of the instrument although there have been some uses reported in the scientific literature.

### Optical Spectroscopic Techniques

Optical spectroscopic techniques are attractive for online analysis as remote sampling by fiber optics can

**Figure 1** (A) Steps involved in offline analysis. Time between sampling and a control decision being made can be days. (B) Steps involved in online analysis. Results obtained in seconds or minutes.

be employed. Fiber optic technology allows a probe to be placed directly into the stream or reactor and measurements made. This removes the need for a sample conditioning system (SCS) that many other online techniques require to regulate the flow rate, temperature, and pressure of the sample and perhaps also to remove particulates. Disadvantages of having an SCS include delays between sampling and analysis, and flushing between samples. It has also been reported that 90% of problems experienced by utilizing online analysis are traced back to the SCS. Care must be taken to ensure that the calibration procedure used takes into account probe fouling, temperature/pressure effects, presence of particulate matter, and any other interferences as there is no SCS present. By using fiber optics, the instrument can be kept out of hazardous areas and can be stored in a safe analyzer house. Different probe designs can be used to make either absorbance or diffuse reflectance measurements. These probes can be inserted directly into the process stream at the point of interest or be placed in a side stream. Contingency plans are necessary in the event of probe fouling. A quick and safe procedure is required to remove and clean the probe without having to close down the process or the stream affected.

Multiplexing, where multiple sampling points can be analyzed with a single instrument, is possible with spectroscopic techniques. Fiber optic cables going to different sampling points can share the energy from the optical source either by splitting the light between the different fibers (space multiplexing) or by passing all the energy down each fiber in turn (time multiplexing).

Ultraviolet (UV)–visible spectrometry, near-infrared spectrometry, mid-infrared spectrometry, and Raman spectrometry have all been used for online process analysis (including inline and noninvasive applications).

**UV–visible spectrometry** UV–visible spectrometry has been used to monitor *in situ* the dissolution of pharmaceutical products, the monitoring of batch reactions, and to monitor antioxidants in a polymer melt. Online UV–visible spectroscopy has also found use in the determination of metals in electroplating bath waste waters.

**Mid-infrared spectrometry** Mid-infrared spectrometry (MIR) has disadvantages that have hindered the widespread acceptance of the technique for online analysis. The wavelength of light used in mid-infrared spectrometry is highly attenuated by silica optical fibers. This limits the length of optical fiber that can be used for distancing the instrument from

the process. Special fibers have been produced, e.g., chalcogenide, which have a lower attenuation for mid-infrared wavelengths, but these fibers are expensive and they still have a very limited throughput which means that they can only be used over short distances. The fundamental absorptions in the mid-infrared region are very strong. If mid-infrared spectrometry was being used for the analysis of major constituents in a process stream, very short pathlengths would have to be employed to ensure the absorptions were not strong enough to deviate from the Beer–Lambert law. By using short pathlengths, there is a danger of small particulates in the process stream blocking the space between the windows of the cell. The problem of obtaining a short pathlength can be rectified by using an attenuated total reflectance (ATR) probe. ATR probes have some disadvantages though. For instance, they are susceptible to fouling and scratching of the surface, and the calibration has to be carried out carefully, as the ATR response is not always linear. ATR is affected by changes to the temperature and refractive index of the liquid being measured which also complicates the calibration procedure.

**Near-infrared spectrometry** Near-infrared spectrometry provides a vibrational spectrum of an analyte over the wavelength range of 1000–2500 nm ( $10000\text{--}4000\text{ cm}^{-1}$ ) produced by overtones and combinations of the fundamental vibrations of the chemical bonds in the analyte. Compared to the mid-infrared region, the near-infrared region is limited in its ability to provide detailed qualitative information of chemical structures due to the wide, overlapping bands that are observed. However, near-infrared spectrometry is very useful for providing quantitative information of molecules containing OH–, NH–, and CH– bonds.

Near-infrared spectrometry is preferred to mid-infrared spectrometry for making online measurements of a chemical process for a number of reasons. As it is desirable to keep an analytical instrument remote from the process, optical fibers are used to transport light to and from the flow cell/probe used for making the measurement. Unlike online MIR, silica fibers of a few hundred meters in length can be used to connect a near-infrared spectrometer instrument to the measurement probe. Absorptions in the near-infrared region are 10–100 times less intense than those in the mid-infrared region and because of this longer pathlengths ( $\sim 1\text{--}10\text{ mm}$ ) can be employed. Although the spectra obtained in near-infrared spectrometry are highly convoluted, precise quantitative information can be obtained by employing chemometric techniques when building a calibration model.

**Raman spectrometry** Raman spectrometry has the potential of being a very powerful technique in process analysis and has many advantages. Noncontact measurements can be made of solids and liquids, and fiber optics can be used to transmit the incident and scattered light, which means that *in situ* measurements can be made in harsh process environments. Raman spectrometers require only electricity to operate; cooling water, gases, and other services are not required. The technique can be used to measure analytes in aqueous solution, unlike infrared techniques, which give large absorptions for water. Another major advantage of Raman spectrometry is that glass can be used for cell windows. This means that laser light could be directed onto a sample through a glass window on a pipe or in the side of reactor, and the scattered light collected through the same window. This removes the problems of probe fouling that can be encountered with inline Raman, near-infrared, and mid-infrared spectrometries.

### **Mass Spectrometry**

Online mass spectrometry is very useful for obtaining process information concerning the molecular composition and structure of unknown compounds and for monitoring an analyte in a complex matrix, and has been used in many applications in the analysis of gaseous streams. Very little research has been carried out into the introduction of, and subsequent analysis of, liquid samples into a process mass spectrometer.

### **Nuclear Magnetic Resonance Spectrometry**

Nuclear magnetic resonance (NMR) spectrometry is a widely used analytical technique for the analysis of many different materials including organic chemicals, inorganic complexes, and large biological molecules. At the moment it is not commonly used in process analytical chemistry. This is partly due to NMR techniques being rather complicated and the signals obtained can be difficult for non-NMR specialists to understand. NMR instruments can be expensive and the technique is much less sensitive than others, e.g., MIR spectrometry.

However, NMR has the potential of being very useful in process analysis due to it being a noncontact and nondestructive technique. Another problem that was faced when NMR was initially tried as an online application was that laboratory instruments were simply moved into the plant. Process operators found problems in the calibration and maintenance of these instruments. Recently, small, dedicated NMR systems have been developed, which in turn has led to more reports of online NMR. Time domain measurements (low field, low resolution) are far more

common than frequency domain measurements (low field, high resolution).

### **Electroanalytical Techniques**

Electroanalytical techniques are not as widely used in process analysis as spectroscopic or chromatographic techniques, but are used in a number of applications. Conductivity measurements are often made to determine the concentration of ionic species in a solution, e.g., in a water demineralization unit, or to monitor the salt content of brine. Voltammetric and amperometric measurements have been used to determine the concentrations of metals in solutions, e.g., waste effluents. Ion-selective electrodes can be used to make potentiometric measurements to determine the concentrations of specific ions, and coulometric measurements have been used in process analysis to measure sulfur-containing compounds.

### **Choosing the Right Technique**

Choosing the best analytical technique to use for a particular application is rarely a straightforward task with many factors needing to be taken into account. The nature of the process stream often rules out a number of techniques, e.g., mass spectrometry and gas chromatography would not be considered for monitoring a blending process in the pharmaceutical industry. Often the nature of the process stream may determine the kind of sampling that is required, e.g., a highly corrosive stream may be more suited to a noninvasive technique rather than a technique that requires a probe to be inserted into the stream or reaction vessel. A full feasibility study should be carried out to determine the best technique to use. Often, the simplest option is by far the best, e.g., if the UV absorbance at a particular wavelength is shown to be selective and sensitive enough to give the required information, then a filter photometer will be much simpler and cheaper to install than online/inline UV-visible spectrometer.

Once a technique has been decided, a decision then has to be taken on which of the available instruments from different suppliers is to be purchased. Parameters that would have to be taken into consideration for this decision include cost, accuracy, precision, limit of detection, dynamic range, weather proofing, ease of calibration, materials of construction of wetted parts, power requirements, internal performance checking, running costs, and vendor support. Often the reputation of the potential instrument vendors can sway the decision on what instrument to purchase.

The technologies and philosophies used in online analysis, i.e., real-time *in situ* analysis, have also found use in environmental analysis and in medicine.

## Introduction

A process chromatograph is an environmentally suitable automated device that measures one or more chemical components in one or more process streams and presents the results in a usable format. A process chromatographic system includes the associated sample system, utilities, waste handling, and data communication as well as the instrument itself.

In most cases, process chromatography is done in the gas phase. Many improvements have been made to liquid chromatographic systems that make them suitable for process use, but this article will focus only on process gas chromatography (PGC).

Process analyzers, whether chromatographs or other analytical technologies, are often compared with their laboratory counterparts. It is instructive to look at some of the differences between a laboratory gas chromatograph (LGC) and a PGC.

Sample introduction for an LGC is usually done with a manual or automated syringe that pierces a septum. A PGC introduces sample with a valve. The process equivalent of an autosampler is a set of stream-switching valves, which are used to choose the sample point of interest. The PGC must also be able to extract an aliquot of sample from a moving process stream some distance away from the analyzer. This requires a means of preserving the state of the sample and delivering a precise amount to the chromatograph without human intervention. Methods for accomplishing this are discussed in more detail below.

An LGC typically uses temperature programming to enhance separation. The PGC is more likely to be run at an isothermal oven temperature, often using multiple columns, with column-switching valves being employed to enhance the separation.

LGCs use mainly capillary columns, while PGCs still use packed columns. PGC with capillary columns is becoming more popular, but criteria such as detector compatibility, sample capacity, robustness, and temperature effects must be considered.

Detectors for lab and process instruments are very similar, but the digitized data may be handled differently. Lab instruments are designed to produce a visually readable report. Process instruments can usually produce a visual report, but their main function is to provide the data to another computer, which often uses the information to control the chemical process.

To summarize, a LGC is designed to be interactive and flexible and is able to handle a variety of samples. A PGC is designed to be independent and robust and is optimized for a particular type of sample.

## Service and Maintenance of Process Chromatograph

When considering the total cost of a process chromatograph, the cost of ongoing maintenance and service is frequently neglected. However, all process chromatographs need periodic maintenance to run reliably, and so planned maintenance should be included in any cost analysis.

### Consumables and Preventative Maintenance

Replacement of consumables can generally be considered routine for gas chromatography as large

The technologies and philosophies used in online analysis, i.e., real-time *in situ* analysis, have also found use in environmental analysis and in medicine.

## Introduction

A process chromatograph is an environmentally suitable automated device that measures one or more chemical components in one or more process streams and presents the results in a usable format. A process chromatographic system includes the associated sample system, utilities, waste handling, and data communication as well as the instrument itself.

In most cases, process chromatography is done in the gas phase. Many improvements have been made to liquid chromatographic systems that make them suitable for process use, but this article will focus only on process gas chromatography (PGC).

Process analyzers, whether chromatographs or other analytical technologies, are often compared with their laboratory counterparts. It is instructive to look at some of the differences between a laboratory gas chromatograph (LGC) and a PGC.

Sample introduction for an LGC is usually done with a manual or automated syringe that pierces a septum. A PGC introduces sample with a valve. The process equivalent of an autosampler is a set of stream-switching valves, which are used to choose the sample point of interest. The PGC must also be able to extract an aliquot of sample from a moving process stream some distance away from the analyzer. This requires a means of preserving the state of the sample and delivering a precise amount to the chromatograph without human intervention. Methods for accomplishing this are discussed in more detail below.

An LGC typically uses temperature programming to enhance separation. The PGC is more likely to be run at an isothermal oven temperature, often using multiple columns, with column-switching valves being employed to enhance the separation.

LGCs use mainly capillary columns, while PGCs still use packed columns. PGC with capillary columns is becoming more popular, but criteria such as detector compatibility, sample capacity, robustness, and temperature effects must be considered.

Detectors for lab and process instruments are very similar, but the digitized data may be handled differently. Lab instruments are designed to produce a visually readable report. Process instruments can usually produce a visual report, but their main function is to provide the data to another computer, which often uses the information to control the chemical process.

To summarize, a LGC is designed to be interactive and flexible and is able to handle a variety of samples. A PGC is designed to be independent and robust and is optimized for a particular type of sample.

## Service and Maintenance of Process Chromatograph

When considering the total cost of a process chromatograph, the cost of ongoing maintenance and service is frequently neglected. However, all process chromatographs need periodic maintenance to run reliably, and so planned maintenance should be included in any cost analysis.

### Consumables and Preventative Maintenance

Replacement of consumables can generally be considered routine for gas chromatography as large

banks of gas cylinders can be set up to minimize the frequency of cylinder changes. Some moving parts, such as valves, will require periodic replacement of seals, inspection for fouling, corrosion, and so forth. A preventative maintenance program can help avoid unexpected problems. Sample cleanup and elimination of oxygen from the carrier gas can help improve column lifetimes.

### **Electronics**

Most electronic repairs consist of replacing entire printed circuit boards, as opposed to individual electronic components and wiring, which was required in early instrumentation. Cam timers have disappeared, to be replaced by digital electronics. Analog electronics have been minimized in order to preserve the integrity of the signal by digitizing as close as possible to the detector.

### **Software**

As in most instrumentation, process analyzers have undergone a fundamental change from hard-wired controllers, switches, and rotary knobs to microprocessor-based software control. With microprocessor control, more advanced functions have become available. Recent years have seen a trend in the incorporation of self-diagnostic routines in the instrument.

PGCs have the capability to be controlled with menu-driven setup screens or a user program. While the maintenance technician will probably not be required to write any programs, enough knowledge to edit programs and understand their function is useful.

Additional software knowledge is required for understanding how to move data from the analyzer to the process computer. Many analyzers have network capabilities and communicate using specific hardware and software protocols. While much of the inner workings of such networking is shielded from the user, a working knowledge of how the network communicates is required for troubleshooting.

### **Control Charts**

An invaluable tool for troubleshooting and maintenance is the instrument control chart. Anything useful can be control charted, such as detector response factors, deviation from expected retention time, etc., but the analysis results from a check gas is one of the most popular items to chart. The most important information a control chart can show is when the instrument needs maintenance or recalibration. While it may seem like a good idea to recalibrate every day, the act of recalibration has error associated with it, and thus overcalibrating can be as much of a problem as undercalibrating. Statistical tools can

be applied to the control chart trend data to show that a significant change has taken place and thus needs to be addressed. In addition, the control chart shows visually when the change began, if it has occurred more than once in the past, cyclical phenomena due to day–night temperature variation, and so forth. This simple, low-tech chart is one of the most underutilized tools in analyzer maintenance.

### **Sample Systems**

It is often said that most process analyzer problems can be traced to the sample system. While some progress has been made in modularizing sample systems, generally the type of maintenance that must be performed has not changed. In many cases, steam-traced lines have been replaced with electrically heated lines, which eliminate maintenance related to steam traps and steam supply. However, filters must still be replaced, valves must still be maintained, and materials of construction that corroded in the past will still corrode.

### **Applications**

Rather than present a specific application, an attempt is made below to define the criteria that would make PGC a suitable technique. After reading the criteria it becomes apparent that certain process points will usually be good candidates for PGC.

#### **Physical Characteristics of the Sample**

One obvious criterion to consider is the physical nature of the sample. Gas-phase streams are the most compatible, but liquid mixtures can also be accommodated if the boiling points are not too high. Small amounts of high boiling materials present in a sample can build up on the column, which will alter or destroy the column's separation ability. This can sometimes be alleviated by including an appropriate backflush step in the method. If there is an extremely wide range of boiling points in the mixture, vaporization of the sample becomes a little tricky as the high boilers may be discriminated against in the volatilization step. Also, a wide boiling range may require a multicolumn approach for obtaining reasonable separation times.

#### **Chemical Characteristics of the Sample**

The chemical nature of the sample mixture should be considered from both a materials of construction point of view and a chromatographic point of view. Extremely corrosive or reactive materials may not be good candidates for gas chromatography. Column stationary phases can react with some chemicals, and so column compatibility is also an issue. Some samples

are not amenable to vaporization; thermal instability can cause components in the sample to degrade.

### Safety

Some sample streams are too toxic, flammable, corrosive, etc. to be removed from the process. Since PGC is necessarily an extractive analysis, the sample must be removable from the process safely for PGC to be suitable. Streams of this nature may be handled more easily with a type of analysis that can be done *in situ*, such as spectroscopy.

### Analyte concentration

PGC can be done successfully at sub-ppm levels, but installation, method development, and maintenance are more difficult at extremely low concentration levels. The sample system, for example, might adsorb low levels of an analyte on surfaces, which can result in memory effects between separations.

## Process Sampling and Sample Systems

The main goal of the sampling system is to extract a sample from the process and deliver it to the analyzer in a manner that is timely, robust, and with the composition unchanged. The manufacturing process from which the chromatograph sample is taken may be under different physical conditions from those for which the chromatograph is designed. Therefore, the sample probe and sample system must change the physical conditions of the sample from process conditions to conditions suitable for the analyzer without changing the analytical information in the sample. The pressure, temperature, flow, and phase must be controlled. The pressure can be controlled by means of pumps and regulators. The temperature can be controlled using heaters and coolers. The flow can be controlled using valves and regulators. The phase can be controlled using heaters, coolers, and vaporizing regulators.

The sample point location is dependent upon the purpose, i.e., control or specification analysis. If the purpose of the analysis is to control the operation of, for example, a distillation column immediately upstream, the concentrations in a downstream storage tank may not be related to controllable process parameters. Better control can be achieved by sampling at the location where the concentration is changing the most rapidly in response to process parameters. Even the overhead and bottoms of a distillation column change very slowly in response to a change in distillation column operation. In this case, the best place to sample the column may be near the critical trays, which have large concentration gradients.

## Basic PGC Hardware

The basic components of a PGC are the same in principle as those for a LGC, but there are differences due to the requirement for unattended and continuous operation in the field.

### Carrier Gas

The carrier gas is identical in both PGC and LGC. It is selected based on the component matrix being analyzed and the detectors being used. The common carrier gases are hydrogen, helium, nitrogen, and argon. Hydrogen is usually best suited for high-speed analyses because its usage leads to minimal degradation in efficiency as carrier linear velocities are increased. Both hydrogen and helium are normally used in the analysis of hydrocarbons using thermal conductivity detectors due to the large difference in thermal conductivity between the carrier gas and the hydrocarbon components of interest. Nitrogen is sometimes used for analyzing air samples or for determining components with high thermal conductivities like hydrogen and helium.

PGC carrier gases are usually supplied by banks of high-pressure gas cylinders, often using an automatic manifold that switches from the 'in-use' bank to the 'reserve' bank when the pressure in the former drops below a preset level. The manifold may also be equipped with an alarm that indicates the reserve bank is in use and that the first bank needs to be replaced.

### Injection and Column-Switching Valves

Since PGCs are required to operate automatically and unattended for extended periods, the sample injection valve in these systems is of critical importance. A PGC sample valve must be more robust than the injection apparatus for a LGC.

Column-switching valves are also used routinely in PGC for backflushing, heartcutting, and so forth for increasing the speed of the analysis. In some applications, the same individual valve can be used for both injection of the sample and column switching if ported correctly.

The two types of sample injection valve are the external sample loop and the internal sample loop. External sample loop valves are typically used for injecting vapor samples. The volume of sample injected can be as large as desired and as small as the physical distance between ports and tubing diameter permit. External loop sizes typically range from ~2  $\mu$ l up to 10 ml.

Internal sample loop valves are characterized by a subtended sample volume inside the moving parts of the valve. Volumes of 0.05 to 20  $\mu$ l are typical and

are limited to the size of the groove or indentation that can be made into the internal parts of the valve. The volume can only be modified by changing the internal parts of the valve. Internal sample injection valves are typically used for introducing much smaller quantities of vapor samples or small aliquots of volatile liquid samples.

There is a variety of valves available for PGC. These are classified according to the mechanism by which the ports are switched and include rotary, piston, slider, and diaphragm valves. The different types of valve all have strengths and weaknesses in terms of operating lifetime, ease of maintenance, and the ability to handle various types of sample reliably. Valveless techniques, based on pressure balancing, are also seeing some application in PGC for column switching.

A rotary valve has partial circumferential grooves on a rotor that turns inside the valve body. The valve body is equipped with ports that emerge radially from the body. When the rotor is moved circumferentially from one position to the other, different combinations of radial ports are connected via the grooves.

Vaporizing liquid injection or piston valves function in a manner similar to syringe injection in LGC. They are typically used to inject moderate to high boiling liquids. Instead of a syringe, the valve contains a grooved piston or valve stem. In the sampling position, the flowing liquid stream passes through the valve and across the valve stem. During injection, the valve stem is inserted through a set of isolating seals and into a heated chamber. The sample aliquot, contained in the groove of the valve stem, is vaporized, and the flowing carrier stream then sweeps it into the column. Sample sizes are typically limited to between a few tenths of a microliter and a few microliters. The large thermal mass of these valves leads to relatively inefficient vaporization compared with laboratory syringe injection systems. This often leads to degradation in separation compared with separations done using laboratory instruments under similar conditions. With capillary columns, splitting of the sample is usually required to prevent column overload.

A slider valve has a flat plate with grooves that connect the valve ports in different combinations, depending upon the plate position. The plate is sandwiched between the body pieces, and the ports project from the body in a perpendicular fashion.

Finally, the diaphragm valve consists of an annular circular groove in the body, alternative ports of which are opened and closed by applying pressure on a diaphragm using either mechanical plungers or simple gas pressure. The diaphragm is sandwiched between the body and the plungers or pressure ports.

By dividing the plungers or pressure ports into two sets and alternatively activating them, two different flow paths are created across the diaphragm, thereby connecting different combinations of ports via the circular groove.

All of the valves are available with air actuators, and some are available with electric actuators. Electric actuators are not usually used in process analysis applications because of both safety and reliability considerations.

### **Packed and Open-Tubular Capillary Columns**

Much process chromatography is still performed using packed columns. Packed columns offer some advantages in terms of ruggedness, stability/reliability, sample capacity, ease of maintenance, range of selectivity, and compatibility with column-switching techniques. However, as process chromatographs decrease in size and as more capillary columns are offered in metal tubing with bonded stationary phases, an increase in the use of capillary columns should be expected.

A packed column typically uses 1–2 mm (called micropacked) or 2–4 mm internal diameter tubing, with some larger columns being used in older gas chromatographs. As its name implies, the packed column is filled with stationary-phase particles. These particles can be coated with a liquid phase, or they can be a stand-alone solid adsorbent.

Stationary-phase particles typically range in size somewhere between 40 and 120 mesh. When coated with liquid, the amount of loading changes the degree of retention on the column. Excessive pressure drops prevent long lengths of packed columns from being utilized. Therefore, separations using packed columns rely heavily on column selectivity rather than column efficiency.

Open-tubular capillary columns typically have an internal diameter ranging from 0.1 up to 0.53 mm. Capillary columns have both advantages and disadvantages over packed columns. Because the carrier gas takes a single flow path through the column, a reduction in the randomness of the mobile-phase path increases the efficiency. In addition, the pressure drop across an open-tubular column is relatively small. Therefore, a long column length can be used. Separations using capillary columns rely mainly on the column efficiency rather than column selectivity. The markedly smaller dimensions of the capillary columns in comparison with packed columns mean that the capillary columns require less carrier gas. Therefore, capillary columns are much more sensitive to temperature, pressure, and flow fluctuations than are packed columns. In addition, the sample

capacity of capillary columns is orders of magnitude smaller than that of packed columns. This can make it more difficult to perform trace analyses on capillary columns, despite their advantage in efficiency and the corresponding sharpness of the peaks.

Short capillary columns can also be used with hydrogen carrier gas to perform high-speed separations. This is due to the fact that the efficiency for short columns does not change dramatically as hydrogen carrier gas flow velocities are greatly increased from the optimal value. Some work has been done with high-speed separations in PGC, but this has been mainly limited to isothermal separations since fast temperature programming (both heating and cooling) is needed to analyze quickly matrices with a wide boiling-point range.

### Chromatographic Column-Switching Systems

In LGC, a single long capillary column is typically used in a temperature-programmed mode to perform the separation. Although this same separation scheme can be used in PGC, the major drawback is the speed of analysis. The solution is to use multiple column trains and column-switching techniques. This allows the chromatograph to be operated in an isothermal mode.

There are predominately four column-switching methods used in PGC. These are (1) backflush, (2) heartcut, sometimes referred to as a 'diverter', (3) trap-bypass, and (4) column selection. Backflush involves reversing carrier flow through the column. It is done in order to remove late-eluting, heavy sample components. This prevents interference in subsequent analysis cycles, prevents damage to the downstream columns, and helps ensure that sample impurities do not accumulate. Late-eluting components can be backflushed to another column that will separate them more efficiently, they can be backflushed directly to another detector to measure them as an aggregate, or they can be discarded to a vent.

Heartcut involves the removal of a chromatographic peak of interest from the background matrix in order to improve the analysis. Heartcut is typically used to transfer a portion of the sample to a second column so that a minor component can be measured without interference. It can also be used in general to reduce tailing from upstream columns and to remove other sample components that might interfere with the analysis.

Trap-bypass involves momentarily trapping part of the sample in a 'lights' column and allowing heavier components to bypass this column. It is typically used to analyze a component matrix with a wide boiling-point range using a single column train. This operation is of less importance today with the advent

**Figure 1** Chromatograph diagrams (L, lab; P, process). L1, column compartment; P2, column and valving compartment; L2, autosampler; P2, sample handling valve(s); L3, pneumatic connections (rear); P3, pneumatic connections (side) and regulator compartment; L4, user keypad and electronics; P4, electronics compartment; L5, data and remote control connections (rear); P5, process computer and local or remote control connection (side); L6, split/splitless injector with septum; P6, process sample input to inject valve and return outlet; L7, detector and vent; P7, detectors (interior).

of parallel chromatography using multiple column trains and detectors.

Finally, column selection allows multiple column trains to be merged alternately together while maintaining a constant carrier gas flow. The side that is selected at any moment in time is transferred downstream for detection, while the other stream is sent to vent. This configuration prevents the two column trains from interfering with each other. This is also of less importance due to the use of parallel chromatography.

Valve configurations for performing the column-switching operations noted above using six-port valves are shown in **Figure 1**. Both the deactuated and actuated states are shown for clarity. It should be noted that these valve-switching schemes could also be designed using 10-port valves. In the case of backflushing, a single 10-port valve can be configured to both inject and backflush the sample if desired.

### Detectors

Among the variety of detectors, only the thermal conductivity detector (TCD) and the flame ionization detector (FID) are in broad use in PGC. The flame photometric detector, typically used for measuring trace sulfur containing species, and the photoionization detector, predominately used in environmental monitoring, also see some usage. The variety of detector types available for PGC tends to be limited because of the requirements for robustness and sensitivity to a variety of stream components. In addition, many PGC detectors are not optimized for use with capillary columns.

**Figure 2** Schematic of various valve configurations.

Thermal conductivity detectors in PGC are universal detectors in that they can be used to measure any component (Figure 2). Typically, TCDs are used to measure percent level components, but because it is a concentration-sensitive detector, the TCD can be designed for lower level analyses by optimizing the detector volume and sensing elements. TCDs used in PGC utilize either filaments or thermistor beads as their sensing elements. Filaments have the advantage that they can be operated at higher temperatures, but they are more prone to failure than are thermistors. The sensitivity is mainly dependent on the detector temperature and the thermal conductivity difference between the carrier gas and the component of interest.

FIDs are most often used in PGC to measure trace-level components because of their high sensitivity. The FID responds mainly to hydrocarbon-containing components. Therefore, it cannot be used for measuring some components such as fixed gases. The FID is a mass-sensitivity detector.

Most modern PGCs can handle simultaneous data acquisition from multiple detectors. Acquisition rates for most PGCs are high enough for integrating relatively sharp peaks properly. Only in the case of very high speed analyses are higher acquisition rates needed.

Peak integration in PGC is accomplished using fixed integration (often called fixed gating) or slope-based integration, similar to that used in LGC. Fixed integration uses start/stop gates that are fixed in time. It has the advantage of being very stable but can be difficult to implement with closely spaced peaks. Large errors can also occur if the peak elutes outside the start/stop gate times. On the other hand, slope-based integration is very good at handling closely spaced peaks and minor retention time drifting, but if the slope detection parameters (typically threshold and peak width) have not been carefully adjusted, it has a tendency to stop integrating a component suddenly when the concentration drops below a certain level.

## Ovens

Temperature control in gas chromatography is critical to achieving stable chromatographic retention times. Although most PGCs are installed in climate-controlled shelters, they must still be designed for installation in an outside shelter, where they are only protected from wind, rain, and dust but not from ambient temperature extremes.

Most PGC separations use isothermal ovens. Although temperature programming can also be used in PGC, it is relatively slow and usually requires installation of a special auxiliary oven. In addition, injectors and detectors are often neither closely coupled to the temperature-programmed oven nor independently heated. This can lead to a reduction in efficiency compared with a similar laboratory measurement.

PGC ovens today are heated electrically. Because the instrumentation must be able to be operated in electrically classified areas, care is taken by the manufacturers to ensure that the skin temperature of the heaters does not exceed specified limits. This can limit the speed at which the oven heats up and the maximum operating temperature that can be achieved. PGC ovens also tend to be fairly large in order to accommodate a number of valves, columns, and detectors.

Two types of ovens are used, the thermal mass or airless oven and the air-bath oven. The thermal mass oven consists of a thick metal enclosure that is heated with cartridge heaters. It is slow to heat up from ambient conditions to moderate temperatures but is very well suited to higher-temperature applications. Air-bath ovens rely on forced circulation of heated air throughout them for maintaining a uniform temperature. Although air-bath ovens heat up to moderate temperatures more quickly than do thermal mass ovens, the skin temperature of the heater element often imposes severe restrictions on the upper temperature limit. Fortunately, most PGC

methods operate at oven temperatures that are below 100°C.

### Basic Utilities and Connections

In addition to the sample inlet and sample return lines, PGCs require electrical power, utility air for valve operation and temperature control, carrier gas, fuel gas and air for FIDs, and signal cables. Sometimes, both digital and analog signal cables are used. The carrier gas, fuel gas, and air for the FIDs must be of high purity. In some installations, utility air is also used for air purging for maintaining electrical code conditions. Utility needs must be considered and accommodated early in the design phase of the process chromatographic system because there are often long distances between the nearest utility source and the chromatographic site.

### Introduction

Electrochemical methods are not as widely used in process analysis as spectroscopic methods and methods based on measurement of physical rather than chemical properties of the material to be analyzed or characterized. Calibration of the analyzer is always a problem and no general procedure can be recommended or applied because it depends on the particular application and analytical method. Poisoning and deactivation of the active surface of the electrode shortens the lifetime of the sensors. Accumulation of static electricity on the body of the sensor creates extra noise.

The advantages of electrochemical methods are that the signal is electrical and no transformation is required for transferring the information to control units. Some of the methods are rather specific and therefore can be used to detect only the species of interest. Other methods are rather nonspecific but can be used to advantage to detect only certain types of compounds such as ionic species in conductimetric measurements.

All electrochemical methods are based on the interaction of electrical energy and matter. The measurements are done in an electrochemical cell where the sample and at least two electrodes are placed. The electrochemical cell possesses a large variety of concentration-dependent physical characteristics that may be exploited for chemical analysis. The methods are mainly used in analysis of aqueous samples but are also applicable to nonaqueous solutions and gases. In most of the methods one concentration-dependent electrical parameter, like voltage, current, resistance, or charge, is measured while the others are kept constant or manipulated to receive the desired response that correlates to the sample composition.

The analytical methods can be divided into different groups depending on the parameter measured. A schematic presentation of the methods is shown in **Figure 1**. The presentation is based on the recommendation of the International Union of Pure and Applied Chemistry. The methods are first divided between those where either the response depending on a reaction at the electrode or a bulk property of the sample is measured. Measurement of electrical capacity of the cell and conductivity of the sample belong to the latter category. In the conductivity measurements the bulk ohmic impedance of the cell is measured. It is customary to report the conductance of the cell as the function of concentration of ions in the sample. All ions, anions and cations,

methods operate at oven temperatures that are below 100°C.

### Introduction

Electrochemical methods are not as widely used in process analysis as spectroscopic methods and methods based on measurement of physical rather than chemical properties of the material to be analyzed or characterized. Calibration of the analyzer is always a problem and no general procedure can be recommended or applied because it depends on the particular application and analytical method. Poisoning and deactivation of the active surface of the electrode shortens the lifetime of the sensors. Accumulation of static electricity on the body of the sensor creates extra noise.

The advantages of electrochemical methods are that the signal is electrical and no transformation is required for transferring the information to control units. Some of the methods are rather specific and therefore can be used to detect only the species of interest. Other methods are rather nonspecific but can be used to advantage to detect only certain types of compounds such as ionic species in conductimetric measurements.

All electrochemical methods are based on the interaction of electrical energy and matter. The measurements are done in an electrochemical cell where the sample and at least two electrodes are placed. The electrochemical cell possesses a large variety of concentration-dependent physical characteristics that may be exploited for chemical analysis. The methods are mainly used in analysis of aqueous samples but are also applicable to nonaqueous solutions and gases. In most of the methods one concentration-dependent electrical parameter, like voltage, current, resistance, or charge, is measured while the others are kept constant or manipulated to receive the desired response that correlates to the sample composition.

The analytical methods can be divided into different groups depending on the parameter measured. A schematic presentation of the methods is shown in **Figure 1**. The presentation is based on the recommendation of the International Union of Pure and Applied Chemistry. The methods are first divided between those where either the response depending on a reaction at the electrode or a bulk property of the sample is measured. Measurement of electrical capacity of the cell and conductivity of the sample belong to the latter category. In the conductivity measurements the bulk ohmic impedance of the cell is measured. It is customary to report the conductance of the cell as the function of concentration of ions in the sample. All ions, anions and cations,

**Figure 1** Classification of electroanalytical techniques.

contribute to the conductance and therefore the conductivity method is not specific. Measurement of the electrical capacitance of the cell is also an impedance measurement and the response that is not specific but a bulk characteristic property is related to the dielectric constant of the sample.

The methods where electrode reactions are considered can be divided into two categories: either the reaction is at the equilibrium or the electrode is polarized and a transient signal is measured. In the former case a thermodynamic property of the cell is used for analytical measurements, i.e., the equilibrium potential of the cell. The Nernst equation can be used to relate the measured potential to the activity of the analyte. The method can be regarded as rather specific because by the design of the electrochemical cell a rather high specificity can be achieved.

The methods where the electrode reaction is not at equilibrium are numerous. In **Figure 1**, only the two most common methods are considered: voltammetry and coulometry. In voltammetry, the electrical current is measured at different potentials and is linearly dependent on the concentration of the analyte. In coulometric methods, the current is integrated over a period of time giving the charge as the parameter measured. The amount of substance of the analyte is, according to Faraday's law, directly related to the charge consumed in the electrode reaction. Coulometric measurements may be performed either in the constant current or constant potential mode. Voltammetric and coulometric methods are not as specific as the potentiometric methods because

all substances that can undergo an electrochemical reaction at the potential of the experiment and that are present in the sample will contribute to the signal measured.

In the conductivity, potentiometric, and voltammetric measurements the response is correlated to concentration or activity of the analyte usually by using calibration curves. In coulometry, however, the charge measured gives directly the amount of substance and therefore no calibration is needed. However, in coulometry the sample is consumed in the measurements and the problem is that the method requires 100% current efficiency to be reliable. Conductimetry and potentiometry are sample nonconsuming methods. In voltammetry, only an insignificant amount of the sample is consumed and therefore the measurement can be repeated. Only in voltammetric stripping methods of very low concentrations of the analyte the amount consumed at the electrode reaction has to be considered if repeated measurements are to be done.

## Conductivity Measurements

The flow of electricity through the solution is accomplished by the movement of ions. The electrical conductivity of a solution is reciprocal of the bulk ohmic resistance and is associated with the various factors retarding migration of ions through the solution. Concentration of all ions present and their mobilities determine the electrical conductivity of a solution. Mobility depends on the charge and size of the ions, temperature of the solution, and the properties of the solvent like the dielectric constant and viscosity.

Measurement of the electrical conductivity of a solution is normally done in two different ways depending on the type of the sample and the purpose of the measurement by using either contact electrodes or electrodeless (inductive) measurement.

In contact electrode measurement two similar electrodes, normally of platinum and coated with platinum black, are immersed in the sample solution. The conductivity cell is a branch of a Wheatstone bridge. In order to avoid polarization of the electrodes an alternating potential of several volts and frequency  $< 1$  kHz is applied to the cell. The solution resistance is measured with the bridge. In the presence of ions in the sample the equilibrium cell potential and the interfacial impedances are unimportant. The measured conductance,  $G$ , can be expressed by the following equation:

$$G = \kappa \frac{A}{l} \quad [1]$$

where  $\kappa$  is the conductivity,  $A$  is the area of the electrode, and  $l$  is the distance between the electrodes. The unit of conductance is siemens, S, which is the reciprocal of ohm,  $\Omega$ . The conductivity is dependent on the concentration of the solute and is given in **Figure 2** for some common electrolytes in water. The common unit of  $\kappa$  is  $\text{S cm}^{-1}$ .

Conductivity measurement with contact electrodes is used in many different process analytical applications. In all of them the main interest is to detect the presence of ionic species in the sample. The effectiveness of distillation and demineralization units is normally controlled by continuous measurement of the conductivity of the outgoing stream. Any defect in the operation of the unit can immediately be seen in the increase in conductivity. The feeding water to steam turbines has to be as clean as possible in order to avoid corrosion in the system that operates under high pressure and at elevated temperatures. The conductivities of feeding water as well as the condensed steam are also continuously monitored by conductivity measurement. Increased conductivity is an immediate indication of corrosion in the system or leakage in the cooling system. This is of extreme importance in nuclear power plants where among other risks corrosion products may also become activated.

Conductivity measurements are also used in monitoring neutralization and precipitation reactions where the conductivity has its minimum at the equivalence point. Processes where soluble electrolytes are washed from insoluble materials are conveniently monitored by measuring the conductivity of the washing solution. Detection of corrosion and leaks in process heat exchangers are widely monitored by measuring the conductivity of

the streams. Any break in the tubes will result in an increase in the conductivity. Salinity in fresh water and salt water is conveniently determined by conductivity measurement. Pollution sources in fresh-water systems can be located by conductivity measurement because pollution generally increases the content of dissolved material in streams and lakes. The concentration of some gases in air is detected by purging the air through an absorbing solution. Sulfur dioxide is measured by absorbing it in a solution of hydrogen peroxide where sulfur dioxide is oxidized and sulfate and hydrogen ions are produced. Increase in the conductivity can be related to the sulfur dioxide content in the gas flow.

Conductivity or impedance measurements are also used to monitor the curing of an epoxy or a thermoset in the plastics industry. Here, the changes in the electrical properties of the materials give information about the chemical changes that take place in the curing process.

Measurement with the contact electrode cell can be done in samples where the specific conductivity is in the range  $0.1 \mu\text{S cm}^{-1}$ – $10 \text{ kS cm}^{-1}$ .

The electrodeless or inductive conductivity measurement in its essence measures the resistance of a closed loop of solution by the extent to which the loop couples two transformer coils. A schematic drawing of the system is given in **Figure 3**. The primary coil is connected to a transmitter that supplies an alternating voltage. Through the solution loop an alternating voltage is induced in the secondary transformer coil. With constant input excitation signal the induced response will be dependent on the ionic composition of the sample solution. The coils are normally enclosed in the walls of a hollow cylinder

**Figure 2** Conductivity as a function of concentration of some common electrolytes.

**Figure 3** Electrodeless or inductive conductivity measurement.

of inert material such as polyethylene and polytetrafluoroethylene. The cell is immersed in the sample solution that constitutes the loop linking of the coils together.

The electrodeless measurement is used with advantage in applications where the sample solution contains abrasive or fibrous solids and where the conductivity is measured in hot and highly corrosive solutions, or when the sample is an electrolyte of high concentration such as mineral acids, strong bases, and different salts. In all these applications a contact electrode cell cannot be used due to problems of serving the cell and maintaining the electrodes in good working condition. The sensitivity of the electrodeless measurement is low and is restricted to samples of high ionic conductivity. Conductivities in the range of  $1 \text{ kS cm}^{-1}$ – $1 \text{ MS cm}^{-1}$  are normally measured with the electrodeless cell.

## Potentiometric Measurements

In potentiometric measurements the potential of an electrode is measured when no current is drawn through the electrode, i.e., the electrode reaction is at equilibrium. Let us consider the electrode reaction [I]:

where Ox and Red denote the oxidized and reduced forms of the compound, respectively. The number of electrons involved in the electrode reaction is  $n$ . The potential of the electrode,  $E$ , follows the Nernst equation:

$$E = E_0 + \frac{RT}{nF} \ln \frac{a_{\text{Ox}}}{a_{\text{Red}}} \quad [2]$$

where  $E_0$  is the standard electrode potential for the electrode reaction,  $R$  is the gas constant,  $T$  is the absolute temperature, and  $F$  is the Faraday constant. Activities of Ox and Red are denoted by  $a_{\text{Ox}}$  and  $a_{\text{Red}}$ , respectively.

The potential of a single electrode cannot be measured but potential differences between two electrodes can be measured. Therefore, in potentiometric measurements a reference electrode has to be used. The reference electrode is constructed in such a way that it has a constant potential. The most common reference electrodes are the silver–silver chloride and the calomel electrodes.

There are several types of indicator electrodes. The simplest is the electrode of some inert material such as platinum, gold, or glassy carbon. These electrodes are used to measure the oxidation–reduction (redox) potential of the solution. The electrode itself does not participate in the electrode reaction but functions only as an inert electron transferring material.

Measurement of the redox potential is nonspecific and all the redox couples in the sample solution contribute to the total potential.

Redox electrodes are mainly used as sensors in processes involving redox couples. An important application is in the metal plating industries where cyanide has to be removed from the plant effluents. Cyanide is eliminated in alkaline solutions by oxidation with chlorine gas in the first step to cyanate ions and then continuing the oxidation process to produce nitrogen and carbon dioxide as the final products:

Both reactions require close pH control and the completeness of the processes is determined by measuring the redox potential of the  $\text{Cl}_2/\text{Cl}^-$  couple at a platinum electrode. When all cyanide has been entirely oxidized the redox potential of the solution is determined by the  $\text{Cl}_2/\text{Cl}^-$  couple. Chromate ions in the process effluents can also be eliminated by reducing them to chromium(III) by sulfite ions:

The completeness of this reaction is also followed by measuring the redox potential of the  $\text{Cl}_2/\text{Cl}^-$  couple. The mineral ilmenite is used as the raw material in the titanium dioxide process. Ilmenite contains also iron(III), which has to be removed before the precipitation of titanium hydroxide in order to avoid co-precipitation of iron(II) hydroxide that would discolor the final product. Iron(III) is reduced with scrap iron to iron(II). The reduction reaction is allowed to go slightly further to reduce also some Ti(IV) to Ti(III) to be sure that the iron(III) has completely been reduced. This reduction step is followed by measuring the redox potential of the solution.

Another type of indicator electrodes are the ion-selective electrodes (ISEs). The potential of an ISE follows the Eisenman–Nicolson equation:

$$E = E_0 \pm \frac{RT}{n_A F} \ln \left( a_A + \sum_i K_{Ai} (a_i)^{n_A/n_i} + D \right) \quad [3]$$

where  $a_A$  and  $a_i$  are activities of the primary and the interfering ion, respectively.  $K_{Ai}$  is the selectivity coefficient for the interfering ion  $i$ . Charges of the ions are  $n_A$  and  $n_i$ .  $D$  is the detection limit. The positive sign is for cations and the negative sign for anions. It should be pointed out that the ISE responds only to

the activity of the free ion, not to the ion in complex form.

ISEs can be classified into several groups depending on the nature of the ion-sensing membrane. The most common and oldest ISE is the glass electrode for measurement of the hydrogen ion activity in the solution. The ion-sensing membrane is made of special glass that is sensitive toward hydrogen ions. The potential of the electrode is a measure of the pH of the sample solution:

$$E = E_0 - 0.059V \cdot \text{pH} \quad [4]$$

The slope of the electrode response, 0.059 V per pH unit, is valid at 25°C. The internal reference electrode in the glass electrode is a silver–silver chloride electrode. The pH electrode is used in most variable applications in process analysis. Most of them are in pH control of processes, effluents, and wastewater treatment plants. The sodium selective electrode is also a glass membrane electrode. It is primarily used in power plants to detect the presence of dissolved solids because sodium is usually a major portion of such contamination.

There are a number of ISEs where the membrane consists of an inorganic salt of the ion to be measured. Most common of such electrodes are fluoride, copper, chloride, and sulfide selective electrodes. In fluoride electrodes the membrane is made of  $\text{LaF}_3$  and the measurement has to be made within the pH range 5.5–8.5 in a special buffer in order to uncomplex the fluoride ion. The main process analytical applications of the fluoride electrode are monitoring the fluoride concentration in fluorinated drinking water systems and measuring the fluorine in process gases from an electrolysis aluminum plant. The gases are absorbed in citrate buffer and fluoride is determined in the buffer by a fluoride ISE. The membrane of a copper ISE is made of  $\text{Cu}_x\text{S}$ , consisting of both  $\text{CuS}$  and  $\text{Cu}_2\text{S}$ . In process analytical applications the electrode is used, for example, in determining copper in metal plating baths. The membrane of a chloride ISE is made of either  $\text{AgCl}$  or  $\text{Hg}_2\text{Cl}_2$  and mixed with some  $\text{Ag}_2\text{S}$  or  $\text{HgS}$ . The chloride ISE is mainly used in the determination of chloride in plant water, natural and drinking water, plant effluents, etc. The membrane of a sulfide selective electrode is made of  $\text{Ag}_2\text{S}$ . Sulfide ISEs have some applications in pulp-making processes where the process solution contains sulfide ions.

Calcium and potassium selective electrodes have a sensing membrane made of poly(vinyl chloride) (PVC) containing a ligand that forms a complex with the cation. The membrane also contains some additional components. Calcium ISEs are mainly

used in the determination of the hardness of different waters. By changing the composition of the membrane it is possible to measure the total water hardness, i.e., the total concentration of calcium and magnesium. Potassium ISEs have their main applications in clinical chemistry.

When the process waters from wood pulping and bleaching are recycled and reused it becomes important to continuously measure the ion content of the pulp suspension. ISEs based on PVC membranes have been optimized for online monitoring of sodium, potassium, and calcium ions in wood pulp suspensions. Potentiometric measurements with ISEs allow rapid measurements with low-cost instrumentation.

One of the main problems with ISEs in process analytical chemistry is the maintenance of the electrode and especially the calibration of the electrode. The short lifetime and poor selectivity are severe limitations of some ISEs.

Oxygen in stack gases is frequently determined by potentiometric measurement (Figure 4). The core of the sensor is a ceramic-like membrane of zirconium dioxide. Two nets of platinum are placed on both sides of the membrane and the potential difference over the membrane is measured. This sensor obeys

Figure 4 Potentiometric measurement of oxygen gas.

the Nernst equation for the electrode reaction:

where  $\text{O}^{2-}$  is the oxonium ion in the zirconium dioxide crystal structure:

$$E = E_0 + \frac{RT}{4F} \ln \frac{(p_{\text{O}_2})_{\text{II}}}{(p_{\text{O}_2})_{\text{I}}} \quad [5]$$

The partial pressures of oxygen,  $p_{\text{O}_2}$ , on both sides of the membrane are used instead of activities as in electrolyte solutions. When air is used as the reference gas on one side of the membrane, the potential of the sensor will be determined by the partial pressure of oxygen in the sample gas. In some of the latest modifications air as the reference gas has been replaced by solid nickelous oxide in contact with the zirconium dioxide providing a constant concentration of  $\text{O}^{2-}$  ions at the platinum contact electrode.

The zirconium dioxide electrode allows direct (in-line) determination of the partial pressure of oxygen in a steel melt (molten metal bath) within some seconds. The oxygen content is used to calculate the carbon content of the steel.

## **Voltammetric and Amperometric Measurements**

In voltammetric measurements the current at a polarized electrode is measured. The current is produced in the electrode reaction [I] that is forced to take place in one direction by applying an overpotential to the electrode from an external potential source. The current is normally proportional to concentration of the electroactive compound in the sample solution. The electrochemical cell consists of three electrodes: a working electrode at which the reaction takes place, a reference electrode, and a counter electrode. The current in the cell flows between the working electrode and the counter electrode. There are also applications where only two electrodes are used. In polarography, the working electrode is a dropping-mercury electrode (DME). It is not a practical electrode and is only used in some special applications. The main advantages of the DME are the renewable surface and the large overpotential to hydrogen evolution. The most common working electrodes in process analysis are platinum, gold, and glassy carbon.

Voltammetric measurements are done by applying a potential scan to the working electrode. When the potential reaches the range where the analyte will be either reduced or oxidized, a definite electrical current starts to flow. When the current is measured at a constant potential the technique is called

amperometry. All compounds that are reduced (oxidized) at less negative (positive) potentials will also undergo electrode reaction simultaneously with the analyte. This is a severe restriction of the voltammetric methods.

Amperometric methods are used to monitor concentrations of chlorine in drinking water and wastewater treatment plants. The methods are to determine the residual chlorine in water. Chlorine is allowed to react with iodide to produce chloride and iodine. The concentration of the produced iodine is measured amperometrically and is a measure of the chlorine concentration in the sample. Chlorine has also been widely used as a bleaching chemical in pulp-bleaching processes. Chlorine dioxide has replaced chlorine in most of the processes and is readily monitored by amperometry. The best material for the working electrode in these applications is glassy carbon. Measurement of the current at +0.5 V gives the concentration of unreacted chlorine dioxide. At +1.0 V the concentration of chlorite ion as the product of the bleaching reaction can be measured. When concentrations of the residual chlorine dioxide and chlorite ion are measured at a certain stage of the process it is possible to predict the brightness of the final product. In many pulp-bleaching plants hydrogen peroxide has replaced both chlorine and chlorine dioxide as the bleaching chemical. Hydrogen peroxide can also readily be determined by amperometry.

Dissolved oxygen in natural waters and wastewater treatment plants is mainly determined by an amperometric method. The sensing device consists of a gold cathode and silver-silver chloride anode immersed in an electrolyte solution of potassium hydroxide and chloride. The cell is enclosed in a plastic container and is in contact with the sample solution through a thin gas permeable membrane covering the cathode and leaving a thin layer of electrolyte between the cathode and the membrane. The cathode is polarized to a potential where reduction of oxygen takes place. Oxygen in the sample solution penetrates the membrane and is then reduced at the cathode producing electrical current. The current is a measure of the concentration of dissolved oxygen in the sample solution.

Voltammetric methods are also used to monitor concentrations of heavy metals in effluents of metal plants. This is done by anodic stripping voltammetry where the ions of the heavy metals are reduced and plated simultaneously with mercury ions, added to the sample, on a working electrode. The metals will form amalgam in the thin layer of mercury that is formed on the surface of the working electrode. This sampling step is performed at a potential where all

the metal ions of interest are reduced. After this step a positive potential scan is applied and the metals will be reoxidized each at their specific potential. The current produced by each metal is a measure of the concentration of the individual metal ions in the sample as long as the accumulation time and other parameters are kept constant.

The most severe problem with voltammetric methods is the poisoning of the working electrode surface. It can be cleaned by applying potential pulses that are capable of removing the adsorbed reaction products from the surface. The surface can also be cleaned mechanically by bombardment with abrasive grit or by rapid rotation in the presence of plastic abrasion pellets. Strong ultrasound has also been used to clean the electrode surface.

## Coulometric Measurements

In coulometric methods the amount of charge consumed in a reaction is measured. The reaction must be brought to completion. The charge is a measure of the amount of substance consumed in the reaction or reagent produced for complete reaction with the analyte. Coulometric methods rely on Faraday's law:

$$N = \frac{Q}{nF} \quad [6]$$

where  $N$  is the amount of substance consumed or produced by the charge  $Q$ . The fundamental requirement of coulometric analysis is that only a single reaction takes place and that the reaction proceeds with 100% current efficiency. In a coulometric experiment either the potential or the current is held constant or in general the current is integrated over the time of the experiment:

$$Q = \int_t i \, dt \quad [7]$$

One of the most frequently used coulometric process analyzers is the sulfur dioxide measuring instrument. A gaseous sample containing sulfur dioxide gas is first filtered to remove solid particles. It is then led through a solution containing sulfuric acid, potassium bromide, and bromine. Sulfur dioxide reacts with bromine producing sulfate and bromide. The concentration ratio between bromine and bromide is measured potentiometrically with a redox electrode. When the ratio is changed due to sulfur dioxide in the sample gas reacting with bromine, more bromine will be produced in the cell coulometrically from bromide to gain the original concentration ratio between bromine and bromide. The coulometric generation current is the measure of the sulfur dioxide

content in the sample gas. All gases reacting with bromine will interfere. Similar instruments for the determination of hydrogen sulfide and some organic sulfur compounds are used in process analysis. The total sulfur compounds and the different components can be measured by using appropriate scrubbers to remove certain components. The individual sulfur compounds can then be calculated from the differences of the signals.

## Electrochemical Sensors

Chemical sensors are small devices that convert chemical information (concentration, activity, partial pressure) into a measurable signal. A chemical sensor is composed of a recognition part and a transducer part. The recognition part interacts with the target molecules or ions in the sample and the transducer converts the chemical interactions into a measurable signal. If the signal is an electrical signal we talk about electrochemical sensors. Depending on the nature of the electrical signal, electrochemical sensors are further divided into potentiometric, amperometric, and conductimetric sensors. Consequently, the ISEs and the zirconium dioxide oxygen sensor described above may be called potentiometric sensors. Analogously, the amperometric method for determination of dissolved oxygen represents an amperometric sensor. Electrochemical sensors include also a large variety of biosensors, such as enzyme-modified electrodes for determination of glucose, immunosensors, and DNA sensors. Electrochemical sensors are continuously developed and may become important analytical tools for process analysis in the future.

### Introduction

In recent years, the push for improved process control, online quality assurance, higher safety standards, and minimization of environmental impact has extended the interest in online process analysis from the traditional industries, such as chemical manufacturing, mineral processing, and petroleum refining, to other areas, such as biotechnology, food manufacturing, metal smelting, paint production, pharmaceutical industry, water and wastewater treatment. The diverse range of process analysis needed in these industries can be performed either directly with suitable sensors or indirectly in samples taken from the process stream at a controlled rate, with or without sample preparation, such as filtration and addition of reagents. In other words, the required process analysis can be performed online, inline, or offline, and can range from simple physical measurements, such as pressure, temperature, flow rate, density, humidity, and moisture content, to chemical measurements, such as pH, dissolve oxygen, conductivity, and a range of specific chemical composition. Online process analysis is particularly useful for gaining a snapshot of the current state of industrial processes with respect to a selected number of relevant parameters. The resulting signal from the sensor provides an indication of the concentration or other measures of the desired sample constituent(s). This signal may also be used with automated process control systems to maintain optimum process operation. For example, such a controller may be able to detect the difference between a set-point signal and the actual signal obtained from the sensor, and can, in turn, act to initiate a corrective measure(s) to bring the process

operation conditions back to optimum range. Consequently, to gain the best advantage from the results of a process analysis, the sensor must also be able to perform the analysis as rapidly as may be necessary for the corrective measures to be effective. In effect, the chosen sensor is central to the reliable analysis of the process streams and, hence, essential for the effective maintenance of process operation and control. With the aid of advanced computer technology it is possible to accomplish the ultimate in flexible and precise control of processes through combination with online sensors.

In selecting sensors for the analysis of physical and/or chemical components in industrial process streams, several factors must be taken into consideration. **Table 1** lists some of these important factors. It is possible to make some compromise between these factors depending on their relevance to a particular process analysis task.

**Table 1** Important factors in selecting suitable sensors for process analysis

Accuracy	Availability	Capital cost

## Classes and Types of Process Sensors

The two broad classes of sensors that are used for the analysis of industrial process streams are physical and chemical sensors. A selection of each of these classes of process sensors are discussed below.

### Physical Sensors

Despite the considerable development of new sensors and transducers for various chemical substances in recent years, the measurement of physical parameters such as temperature, pressure, density, flow rate, humidity, and refractive index are still very important aspects of industrial process analysis. Some of the

recent developments in the measurement of physical parameters, such as flow rate, temperature, pressure, humidity, turbidity, and moisture content, are discussed below.

**Flow and pressure sensors** A very important parameter that is often measured in most industrial process streams is flow rate. The range of flow sensors that are available for measuring liquid and gas flow rate in industrial process streams is summarized in **Table 2**. Of these, the accuracy, resolution, and cost of ultrasonic flow sensors are attractive and comparable to other flow sensors. Furthermore, it is now possible to use this flow sensor to monitor process

**Table 2** Available industrial process flow sensors

<i>Flow sensor</i>	<i>Measurement approach</i>	<i>Type</i>	<i>Applications</i>
Pressure head flow	Relates a change in pressure drop to a change in flow. Volumetric flow rate is proportional to the square root of the pressure drop	Rotating-vane sealed drum, lobed impeller meters	Liquids and gases for mixture ratio control, distribution of multiple lines, injection of secondary fluid
Positive displacement flow	Uses volumetric displacement principle to determine flow rate		Liquids
Open channel flow	Based on the principles of dilution ratio, or head flow rate relationship or velocity area product		
Ultrasonic flow	Uses piezoelectric transducers mounted either integrally within a flow type section or on an existing pipe together with associated electronics to process the ultrasonic signals. Transmits ultrasonic pulses diagonally through a pipe from the upstream and downstream sides. Measures flow rate from the detected time difference. Measures flow velocity, flow rate, and total flow output. Can also provide flow alarms	Pulse and Doppler	Liquids; can be used with process density analyzers to provide mass flow data
Vortex flow	Uses a circular cylinder across a pipeline and detects frequency of the vortex shedding signal generated. Vortex shedding is detected by sensing the resulting small velocity or pressure pulses	Thermal, ultrasonic, pressure	Liquids and gases
Turbine flow	Uses the proportionality of the fluid flow rate to the speed of revolution of a turbine wheel in a flow stream	Alternating current, direct current	Liquids and gases
Electromagnetic flow	Based on passage of a conductive liquid through a magnetic field, resulting in the generation of a voltage proportional to the average velocity of the liquid slurry		Liquids. Especially for corrosive acids, sewage, slurries, paper pulp. Liquid should have a conductivity of at least $1 \mu\Omega \text{ cm}$

Adapted from Liackman F (1990) *Process Control Engineering* May: 78–84.

flow rate without requiring any special installation at a point in the pipe, as was previously the case. There are many varieties of the clamp-on ultrasonic sensors that can now be used in this way.

A low-cost, low-power-consuming micromachined flow and pressure sensing device has also been reported. This sensor can be used for monitoring pressure and flow rate in clean fluids without particles and without the tendency to coat the channel. The pressure is measured with capacitive or piezoresistive pressure sensors and the flow rate is computed from the pressure drop over a well-defined, hydraulic resistance. Although this device is yet to be used for process analysis in industrial stream, it will gain more use in this area in the future.

**Temperature sensors** Another important parameter that is commonly measured in industrial process streams is temperature. Most chemical and biological reactions in industrial processes are known to be temperature dependent. The reliable and accurate determination of temperature in these cases is of paramount significance. Some of the industrial processes for which temperature measurement is frequently required include water treatment, wastewater treatment, conditioning of drinking water, sewage sludge treatment, and a wide range of chemical and biochemical processes.

The most commonly used temperature sensors for these purposes are thermocouples and resistive temperature detectors (RTDs). The thermocouples are more widely used because they are rugged and relatively inexpensive. These sensors are capable of measuring temperatures between  $-250$  and  $2300^{\circ}\text{C}$ . However, they are not as accurate and corrosion resistant as RTDs.

The temperature of automotive engine exhaust gases is usually monitored with RTDs. A thin platinum-based film is usually used as the sensing element and the resistance of this material increases with increase in temperature. Conduction is minimized by thermally decoupling the sensing element from the sensor body. The exposure of the sensing element to the exhaust gas is via an open housing that acts as a radiation shield. As a result of this unique design, RTDs are very sensitive with voltage drop across the sensing element exceeding  $1\text{ mV }^{\circ}\text{C}^{-1}$  with an accuracy of  $\sim 1.5\%$  and a response time of  $\sim 5\text{ s}$  for a temperature change of  $300\text{--}1000^{\circ}\text{C}$ . These temperature sensors are rugged and easy to set up. They are now commonly used in automotive engine and catalyst diagnostic and control.

In general, most of the available temperature sensors can be used in aqueous and gaseous media, but there are also Teflon-coated temperature sensors

that can be used for measurement in aggressive solutions.

**Turbidity sensor** The online measurement of turbidity and solid content are common practices in wastewater treatment plants. This is particularly significant in biological wastewater treatment, sludge recycling, and in the final effluent where the level of suspended matter provides a useful and immediate indication of the effectiveness of the overall treatment process. The common turbidity sensor used for this purpose is based on the use of an optical infrared scattered light sensor. Unfortunately, the reliance of this sensor on optical measurement is a major disadvantage, as the buildup of particulates on the surface can give incorrect measurement for turbidity and the solid content. The buildup of microorganisms on the surface of this device is a common problem in wastewaters. To remedy this problem, manual cleaning is often required or the use of wiper systems may be employed. However, the sensors equipped with wipers and jutting corners do not always give satisfactory results for the measurement of turbidity and solid content in wastewater treatment plants. Recent developments have led to the introduction of new sensors that incorporate ultrasound cleaning system to minimize or eliminate the buildup of particulate matter and microorganisms on the surface of the sensor. This, in turn, ensures that the sensors last longer and require less maintenance due to the prevention of accumulation of particulate matter from the onset. The ultrasound vibrations also prevent the collection of air bubbles on the surface of the sensor and, hence, ensure reliable measurement of turbidity and solid content. The sensors can measure turbidity within 0 and 4000 FNU and solid content in the range of  $0\text{--}300\text{ g l}^{-1}\text{ SiO}_2$ . These sensors can be used in various applications over several weeks without requiring maintenance.

**Humidity sensors** The measurement of humidity is essential for various industrial process operations, such as in the control of drying plant, ovens, and effluent gases from metal refining furnaces, mineral processing kilns, power plants, chemical plants, and incinerators. Adequate expression of the measured gas pollutant concentrations (on a dry basis) relies on a reliable measurement of the humidity in the process environment.

The range of available ceramic sensors for measuring humidity in industrial process environments can be classified into four categories: (1) ionic, (2) electronic, (3) solid electrolyte, and (4) rectifying-junction types. A solid electrolyte humidity sensor that uses doped strontium cerate has been reported

for high-temperature humidity monitoring. The sensor has been successfully used for reliable measurement in moist air streams and in a combustion rig under conditions where  $>10\%$   $O_2$  is present. Below this oxygen concentration the sensor's response becomes very sensitive to oxygen levels.

**Online moisture sensors** Moisture determination is an important aspect of many industrial processes. The range of available methods for moisture measurement in granular materials and the principles of these methods have been reported in a recent review. Of these, near-infrared (NIR) spectroscopy has gained most use for online moisture measurement in a wide range of granular materials. Also commonly used for moisture measurement in diverse range of granular materials are microwave phase shift (MPS) and microwave attenuation (MA) methods, radio frequency transmission, neutron moderation activation, and direct physical measurement (based on drag force principle) methods. Some of the specific applications of the methods are summarized in Table 3.

Evidently, MPS and MA are the best methods for online measurement of moisture in most materials. However, for materials where most methods are not applicable or have not been attempted, NIR spectroscopy is the method of choice.

### Chemical Sensors

This class of sensors consists of devices that can determine specific chemical composition in industrial process streams by measuring some physical properties, such as voltage, current, electrical or thermal conductivity, absorbance, density, refractive index.

Most of these sensors have gone through considerable developments in recent years and newer versions have been introduced in many cases. The distinct features of these newer or modern chemical sensors that are available for process analysis include improved sensitivity, better precision, better selectivity, faster response time, extended analytical range (component and concentration), capability for simultaneous or sequential multicomponent detection and quantification, improved portability (compactness), and robustness. Some of the newer or modern chemical sensors that are of direct and immediate significance for process analysis in various industrial process streams are described below.

**pH sensors** The acidity or alkalinity of most industrial process streams plays a significant role in the chemical, biological, and physical reactions that take place in the various processes. For this reason, pH is the most commonly measured parameter in most process streams. The solution pH is particularly significant in water and wastewater treatment processes. For example, the continuous online pH monitoring and control are essential in biological treatment of wastewaters where the pH of the water can have significant influence on the activity of the microorganisms that are used in this process. Also, extreme pH conditions in water and wastewater treatment can result in the destruction of metallic components (at  $pH \leq 6.5$ ), solubility of metallic and other components or precipitation of soluble substances. Reliable pH monitoring and control are also essential for various reactions, such as precipitation, neutralization, and detoxification, which are often

**Table 3** Some industrial applications of online moisture sensors

Industrial applications	Online moisture sensors/methods									Best method
	SGM	MPS	MA	NIR	CC	RFT	NMA	LR	DPM

Moisture sensors/methods: standard gravimetric method (SGM); microwave phase shift (MPS); microwave attenuation (MA); near-infrared (NIR); capacitance and conductivity (CC); radiofrequency transmission (RFT); neutron moderation activation (NMA); low resolution (LR); direct physical measurement (DPM) based on the drag force principle.

required in many industrial processes. For example, industrial effluents from breweries and dairies often have to be pretreated in a neutralization plant in order to meet the desired pH range of 6.5–8.5, required for discharge into municipal sewer systems.

For the above reasons, most efforts in the design and production of pH sensors have focused on the development of high-precision sensors for industrial process streams owing to the diverse and often difficult conditions that are experienced in these media. These pH sensors are designed to have long-term stability and extended life, based on the use of industrial-grade electrodes with silver/silver chloride reference electrodes incorporated into gel-polymer electrolytes. Some of the industrial-grade pH sensors use modified gel-solid electrolyte, which is free of silver chloride and, hence, can be used in presence of sulfides.

The design of these industrial pH sensors is superior to those of conventional pH electrodes in terms of failures and durability. The online pH sensors are rugged and can withstand harsh industrial conditions. Various types of these pH sensors are available for use in contaminated sewage, drinking water, emulsions and suspensions, municipal and industrial sewage, polluted wastewater, protein- and sulfide-containing media. These sensors can measure pH in the various process streams between 0 and 14. Most of these also have integrated temperature sensors for automatic temperature compensation and a protection guard for the electrode. Some of the pH sensors have additional features, such as glass breakage detection and lightning protection system.

A special type of these pH sensors are designed as valve assemblies and are designed for installation in pipes or vessels. These assemblies allow the pH sensors to be inserted manually and retracted without interrupting the process stream. They are particularly useful for reliable and safe operation under tough process conditions (pressure vessels). The pH sensors can be recalibrated or cleaned when in retracted position without stopping the process.

**Conductivity sensors** A very significant parameter that gives a measure of the concentration of ions in industrial process streams is conductivity. The continuous measurement of conductivity in process streams is a common practice in the monitoring of boiler feed water, brackish water, demineralization, industrial process media, municipal and industrial wastewater, surface waters, and water treatment. Specific areas of application for conductivity sensors include control of drinking water and ultrapure water quality, determination of nonspecific contaminants, monitoring of salt load in wastewater

treatment plants, and process control in food and pharmaceutical industries.

Most of the development in conductivity sensors in recent years has been in the improvement of the design to enable attainment of better performance. In addition to the conventional two-electrode cells, more advanced design has recently resulted in the introduction of a four-electrode cell that gives a considerably better performance, particularly at the higher conductivity ranges. This new sensor design employs two separate electrode pairs, where the current-free voltage electrodes produce a stable and constant reference potential and a potentiostatic circuit is used to regulate the voltage drop at the current electrodes. The two distinct advantages of this new conductivity sensor design are (1) the elimination of measurement errors caused usually by polarization effect, and (2) the avoidance of contact resistance caused normally by contaminated electrodes. More significantly, these new conductivity sensors are capable of measuring conductivity in process streams in the range of  $0.1 \mu\text{S cm}^{-1}$  to  $2000 \text{ mS cm}^{-1}$ . The analytical conductivity ranges of the new conductivity sensors are higher than those of the conventional two-electrode cell with an upper limit of  $\sim 300 \mu\text{S cm}^{-1}$ , but the lower limit for the latter can be as low as  $0.1 \text{ nS cm}^{-1}$ .

**Dissolved oxygen sensors** In addition to pH and conductivity, the online monitoring and control of dissolved oxygen in process streams is of vital importance for efficient operation of many industrial processes, particularly in aquaculture, limnology, water and wastewater treatment, and water pollution control. For example, the efficient operation of biological nutrient removal in wastewater treatment plants requires precise and continuous measurement of dissolved oxygen level in the process stream. The oxygen level in such a process has significant influence on the activity of the microorganisms that are used and, hence, on the efficiency of the nutrient removal process.

The most significant development in this area has been in the design of low maintenance, mechanically more robust dissolved oxygen sensors with rugged foul-resistant membrane. These new oxygen sensors enable more reliable measurement with minimum sample flow and simple automatic calibration in air. The design of this high-performance dissolved oxygen sensor has resulted in an increasing shift from the conventional two-electrode arrangement. Typically, the new three-electrode oxygen sensor consists of a gold working electrode, a silver reference electrode, and a silver auxiliary (current-carrying) electrode. The two distinct advantages of the new oxygen

sensor are improved accuracy and stability. These advantages are due, in part, to the improved stability of the potential of the reference electrode (with no current flow) in the new sensor arrangement.

Some of the reported successful uses of the new dissolved oxygen sensor include monitoring of boiler feed water, drinking water, denitrification of biological sewage treatment, and heavily polluted industrial wastewater. These oxygen sensors can measure dissolved oxygen in process streams at high ( $0\text{--}60\text{ mg l}^{-1}$ ) and low ( $0\text{--}2000\text{ }\mu\text{g l}^{-1}$ ) ranges with response times between 30 and 180 s.

**Phosphorus and nitrogen sensors** A very important area where the use of sensors for process analysis has gained much interest is in wastewater monitoring. In particular, the use of analyzers for monitoring of nutrients (nitrate, nitrite, ammonium, and phosphate) and organic matters is of considerable interest.

Several online analyzers/sensors based on classical colorimetric methods have been reported for the monitoring of phosphate, ammonia, and nitrate concentrations in wastewater treatment plants. These sensing devices have been used to achieve significant improvements in the efficiency of wastewater treatment plants based on the implementation of a rule-based control strategy.

Table 4 provides a summary of some of the sensors/analyzers for online monitoring of ammonium, nitrate, and phosphate. Most of these involve common colorimetric reactions in automated analyzers.

**Chlorine sensors** Online potentiometric and amperometric chlorine sensors are commonly used to monitor chlorine concentration in process streams. The use of a potentiometric chlorine sensor involves adjustment of solution pH and subsequent reaction with lead iodide ( $\text{PbI}_2$ ) to produce iodine. The resulting iodine is detected potentiometrically by an electrode and is related to chlorine concentration. This sensor has been successfully used for continuous monitoring of chlorine levels in water treatment plants.

The use of an amperometric variation of the chlorine sensor has been reported for monitoring chlorine

dioxide in the bleaching stage of a chemical pulp bleaching. This amperometric sensor can be more widely used for monitoring and controlling the bleaching process in the pulp industry by measuring residual chlorine dioxide and chlorite.

**Online mercury sensor** A computer-controlled online sensor for monitoring mercury in streams and aqueous discharges has been reported. This device is based on the use of a dual-wavelength spectrophotometric analyzer. The monitor operates continuously unattended and can measure  $0.5\text{--}10\text{ }\mu\text{g l}^{-1}$  of mercury. It has facility for sounding alarm from a remote location to the central monitoring station. Figure 1 shows a 20-h segment of the continuous monitoring of mercury at upstream and downstream of East Fork Poplar Creek within the Oak Ridge Y-12 plant in Tennessee, USA.

## Process Analyzers

In addition to the physical and chemical sensors, there are a wide range of analyzers that are commonly used for analyzing chemical substances and/or other chemical characteristics in process streams. Specific examples of these analyzers are described below.

### Process Fourier Transform Infrared Spectroscopy

Fourier transform infrared (FTIR) spectroscopy is particularly useful for online monitoring of polymer composition. Its ability to fingerprint chemical components allows FTIR to determine the constituents of a chemical process. It has been applied to the analysis of solid, liquid, and gaseous process streams. These analyzers can perform complete measurements in as rapidly as one per second. The range of parameters that can be monitored by these analyzers include film thickness, impurities, chemical composition, and polymer curing rate. FTIR can be used for online monitoring of polymer reactions, analyze polymer melt processes, and monitor the gaseous by-products from polymer processing. With the aid of a computer it is possible to determine the concentration of the

**Table 4** Available nutrient analyzers/sensors for monitoring wastewater

Analyte	Chemical method	Alternative
Ammonium	Indophenol blue	Increase pH and measure $\text{NH}_3$ with a gas-sensitive electrode
Nitrate	Reduction of nitrite followed by formation of a purple diazo complex	Absorbance at 205 nm or ion-selective electrode
Phosphate	Molybdenum blue	None

**Figure 1** A 20-h segment of the continuous monitoring of mercury. (Reprinted with permission from Hinton ER, Jr., Rawlins LK, and Flanagan EB (1987) Development of an online mercury stream monitor. *Environmental Science and Technology* 21(2): 198–202; © American Chemical Society.)

constituents or determine their origins in the chemical process by FTIR spectroscopy. The use of fiber optics with FTIR means that the process stream can be monitored without being directly in contact.

Online process analysis of polymer composition has been accomplished by Rheo-Optical FTIR spectroscopy, which involves the measurement of the stress and strain of an elastomer. This approach utilizes the rapid scanning capabilities of FTIR to obtain vibrational spectroscopy data. Strain-induced crystallization that occurs in polymer gives important structural information that can be obtained by FTIR. The stress/strain process was observed by measuring the C–CH<sub>3</sub> in-plane deformation vibration (1126 cm<sup>-1</sup>) and the ν(C=C) absorption band (1662 cm<sup>-1</sup>), which represents the average polymer thickness reference band. This is particularly useful in the adhesive industry for monitoring the characteristics and composition of the resulting polymer when elastomers are blended in a milling process.

FTIR has also been used for online compositional analysis of polymer blends and copolymers from a plant extruder. Varying concentrations of styrene or acrylic polymer were identified from the resulting FTIR spectra. The online monitoring was accurate when temperature fluctuations were ±5°C. The off-line measurements were found to be less accurate than the online measurements.

Hyphenated FTIR systems have also been used to improve the detection of the by-products of the outgassing of polymer processes. A good example of such hyphenated systems is the use of thermal-desorption

gas chromatography/FTIR for the analysis of the outgassing of polymers. This hyphenated system was successfully used to examine numerous thermoplastics, such as polystyrene, polystyrene copolymer, polyacrylate, polycarbonate, polyamide, and polyacetal. An extended version of the hyphenated system incorporates a mass spectrometer and permitted online analysis of the outgassing by-products of thermal degradation of polymers, as well as the elucidation of evolved species.

### Process Near-Infrared Reflectance Spectroscopy

The use of NIR reflectance has gained considerable interest for process analysis in the food, pharmaceutical, petrochemical, and other chemical industries. This method requires little or no sample preparation and involves measurement of the reflectance of a liquid or solid sample relative to that of a standard in the same wavelength series. As illustrated in Table 3, process NIR has gained considerable use for moisture determination in coal, cosmetics, and detergent powders, as well as for protein contents of cereal and grain, and hydrogenation of unsaturated fats and oils.

The use of NIR with fiber optics has also been reported for online monitoring of fuel quality parameters, such as research octane number, motor octane number, olefin, naphthene and aromatics content of gasoline. The online analysis of the fuel quality parameters was obtained without loss of precision and accuracy when compared with the traditional motor test.

### Dispersive and Nondispersive Infrared Process Analyzers

In addition to FTIR and NIR, three categories of infrared analyzers have gained considerable interest in the process analysis of liquid and gaseous streams. These infrared analyzers include (1) dispersive, (2) nondispersive, and (3) bandpass optical filter. The two commonly used categories are the dispersive and nondispersive infrared analyzers.

The dispersive infrared analyzer, which is similar to the double-beam spectrometer, is capable of analyzing components of liquid and gaseous process streams. In contrast, the nondispersive infrared analyzer, which is a filter photometer, is more suited to the selective analysis of components of gaseous process streams. In general, the design and operation of nondispersive infrared analyzers are simpler than those of dispersive infrared analyzers. Also, the use of filtering techniques with the nondispersive infrared analyzers increases the selectivity of the analysis, but this can also reduce sensitivity. These infrared analyzers are commonly used for the analysis of

**Figure 2** Detection of an unknown discharge in the wastewater influent with the conducting polymer sensor array. (Reproduced with permission from Bourgeois W, Gardey G, Servieres M, and Stuetz RM (2003) A chemical sensor array based system. *Sensors and Actuators B* 91: 109–116; © Elsevier.)

gaseous substances, such as carbon monoxide, carbon dioxide, nitrogen oxides, sulfur dioxide, cyclohexane, vinyl acetate, ammonia, dioxane, Freon, and carbon tetrachloride in industrial processes and in ambient air monitoring station.

### Other Process Analyzers

The range of other available process stream analyzers includes process gas chromatograph, process high-performance liquid chromatograph, and online potentiometric analyzers. Process gas chromatograph is different to those commonly used in laboratories, particularly in its design to provide analytical results at a response time that is comparable to changes taking place within an industrial process stream. Also, it operates continuously, analyzing one or more process stream components. This analyzer is commonly used in the petrochemical and refining industries.

Interest in process high-performance liquid chromatography has only developed in recent years, but is gaining use in food and pharmaceutical industry. However, the resolution of problems associated with sampling, maintenance of column condition, and reliability are more difficult to accomplish than for process gas chromatography.

Online analysis of inorganic ions and dissolved gases has also been accomplished by use of potentiometric analyzers that employ specific or selective ion electrodes for continuous analysis of the individual components. This type of analyzer is commonly used for continuous online monitoring of chloride, cyanide, and fluoride in water, effluent, and

other process streams. The unique advantage of these analyzers is that their measurements are often not affected by the color and presence of suspended materials in the process streams. Also, their accuracies are comparable to those obtained in laboratory environments.

### New and Emerging Sensor Technologies

A much wider range of physical and chemical sensors will be available for process analysis in the future. Currently, there are several new sensors that have been developed, such as biosensors, conducting polymer sensors, electronic noses, and electronic tongues, to name a few, that will gain more interest in process analysis in the future. A recent application of one of these new sensors involves the use of a conducting polymer sensor array coupled with a headspace generating flow cell for a successful continuous monitoring of sudden changes in wastewater quality over a 12-month period. **Figure 2** shows that this sensor array is capable of detecting a pollution episode in wastewater, as evident from the rapid increase in the responses of four of the eight sensors in the array. The observed increases reportedly correspond to a strong petroleum smell in the wastewater at the sewage works.

This is only one of the many new dimensions of process analysis that will be opened up with the introduction of the new and emerging sensor technologies in this area in the future.

## Introduction

A transient elastic wave spontaneously generated by abrupt localized changes of strain within a body is the definition of acoustic emission given by Eitzen and Wadley. Acoustic emission monitoring is the name of the associated technique that finds application in a range of areas from nondestructive testing (NDT), machinery condition monitoring to process analytical technology.

Serious work on acoustic emission monitoring started in the 1950s. This mainly featured NDT of composite materials, storage vessels, and aircraft structures.

Since the 1990s, there have been significant developments in the application of acoustic emission to monitoring processes including fluidized beds, high-shear granulation, crystallization, entrainment of solid particulates, and liquid droplets in gas streams. All of these are dynamic processes involving at least two phases.

Acoustic emissions are broadband signals whose frequencies range from a few hertz to several

megahertz. However, acoustic emission is usually monitored at ultrasonic frequencies (50 kHz–1 MHz). This leads to a signal-to-noise ratio benefit as high frequencies are attenuated more strongly than low frequencies, which results in low background signals.

The key features of acoustic emission that make it attractive for process monitoring are:

- *Noninvasive* – this makes installation very easy. The transducers are attached to the outside of the vessel. There is no need to breach the wall of a vessel (in the case of a pressure vessel this is a particularly costly procedure); there are no sensor contamination issues.
- *Real-time information* – acoustic emission responds to real-time events. This means that acoustic emission is very suited to control applications.
- *Intrinsically safe* – acoustic emission transducers are often rated intrinsically safe so that they can be installed in a hazardous area without the need for purged or explosion-proof enclosures. This makes deployment easy in locations such as petrochemical plants.

## Theory

### Acoustic Emission Sources

In NDT applications, the main source of acoustic emission is the rapid release of energy during crack

## Introduction

A transient elastic wave spontaneously generated by abrupt localized changes of strain within a body is the definition of acoustic emission given by Eitzen and Wadley. Acoustic emission monitoring is the name of the associated technique that finds application in a range of areas from nondestructive testing (NDT), machinery condition monitoring to process analytical technology.

Serious work on acoustic emission monitoring started in the 1950s. This mainly featured NDT of composite materials, storage vessels, and aircraft structures.

Since the 1990s, there have been significant developments in the application of acoustic emission to monitoring processes including fluidized beds, high-shear granulation, crystallization, entrainment of solid particulates, and liquid droplets in gas streams. All of these are dynamic processes involving at least two phases.

Acoustic emissions are broadband signals whose frequencies range from a few hertz to several

megahertz. However, acoustic emission is usually monitored at ultrasonic frequencies (50 kHz–1 MHz). This leads to a signal-to-noise ratio benefit as high frequencies are attenuated more strongly than low frequencies, which results in low background signals.

The key features of acoustic emission that make it attractive for process monitoring are:

- *Noninvasive* – this makes installation very easy. The transducers are attached to the outside of the vessel. There is no need to breach the wall of a vessel (in the case of a pressure vessel this is a particularly costly procedure); there are no sensor contamination issues.
- *Real-time information* – acoustic emission responds to real-time events. This means that acoustic emission is very suited to control applications.
- *Intrinsically safe* – acoustic emission transducers are often rated intrinsically safe so that they can be installed in a hazardous area without the need for purged or explosion-proof enclosures. This makes deployment easy in locations such as petrochemical plants.

## Theory

### Acoustic Emission Sources

In NDT applications, the main source of acoustic emission is the rapid release of energy during crack

propagation as solid materials are subjected to tensile stress. The amplitude of the acoustic wave (stress wave) is proportional to the area of the new fracture surface, the velocity of fracture, and the square of the yield stress.

In process analysis, the sources of acoustic emission are typically the impact of particles on the walls of a vessel (e.g., fluid bed, granulator, pipe), the deformation or fracture of particles, and the oscillation of gas bubbles.

A single particle impact produces a single burst of acoustic emission. This is referred to as burst emission. These are also the typical acoustic emission signals generated in NDT applications. Cracks propagate in a jerky manner, every time they move they produce a burst of acoustic emission. These bursts are normally well time-resolved, i.e., the length of the burst is short compared with the interval between bursts. This has led to the development of a number of measurement techniques based on event counting or timing. However, these techniques are usually unsuited to process analytical work. In these applications, such as monitoring a fluid bed reactor, the impacts are so frequent that it is impossible to resolve individual events. This type of acoustic emission is referred to as continuous emission (Figure 1).

The acoustic emission arising from a particle impact is related to its velocity, mass, and how the particle interacts with its target. When a particle impacts

with a surface the interaction may be elastic, plastic, or cause fracture of the particle.

Elastic impact is a nondamage process. The intensity of the acoustic emission is controlled by the kinetic energy of the impact.

Plastic impact is similar to elastic impact except that the surface or particle is modified in shape as a result of plastic deformation.

Acoustic emission caused by single particle impact is reasonably well understood. It is possible to quantitatively analyze acoustic emission signals to predict particle size. The analysis is based on a deconvolution of the acoustic emission source function from the measured acoustic emission signal. The measured acoustic emission signal  $V(t)$  is a convolution of the acoustic source  $S(t)$ , the propagation function through the metal plate  $G(t)$ , and the detector response function  $D(t)$ , where  $*$  represents convolution:

$$V(t) = S(t) * G(t) * D(t)$$

All the information of interest is contained in the acoustic source function. The theory works well for low-velocity impacts where the collisions are elastic but may be extended with some modifications to include plastic deformation. The method is nonempirical (requiring no independent calibration). However, the measurement requires a calibrated broadband sensor, the particles strike a well-characterized metal plate, at a known velocity, and the burst acoustic emission signals must be separated in time by  $\sim 1$  ms. In process analysis, it is unlikely that all (or any) of these requirements can be met.

Acoustic emission from large assemblies of particles, such as encountered in a fluidized bed or granulator is not well understood and there is virtually no published research. In contrast, there is a rich history of research on acoustic emission producing sands. These sands are known as booming and squeaking sands and occur naturally in deserts and beaches. They have been known of for thousands of years. Marco Polo in 1295 described evil desert spirits 'at times filled the air with the sounds of all types of musical instruments and also of drums and the clash of arms'. These sounds are produced when the sands are stressed or put into motion by an avalanche. Squeaking sands usually produce acoustic emission in the audible range 100 Hz–1 kHz. Booming is described as a 'beat frequency' in the 1–10 Hz band. There has been much speculation on the mechanisms responsible for the production of this acoustic emission.

Both observational and laboratory research have failed to come up with a complete or satisfactory theory explaining this phenomenon. The majority of evidence supports the theory that squeaking is caused

**Figure 1** Types of acoustic emission – (A) burst and (B) continuous.

by intergranular friction. The combination of narrow particle size distribution, high degree of sphericity, and resistance to shear are thought to be critical factors leading to 'squeaking'. Booming sands are characterized by unusually smooth surface textures of the granules.

Because of the lack of detailed theory and the difficulty of applying what is known to practical situations most process acoustic emission work has focused on the development of highly empirical models. The basis of these is the comparison of acoustic emission signals with those measured under known conditions.

### Acoustic Wave Propagation

The link between the source and the signal detected by the sensor is the acoustic wave. Much of the complexity seen in an acoustic wave is generated as the wave travels through the medium. Any understanding of the acoustic emission signal requires knowledge of the acoustic waves.

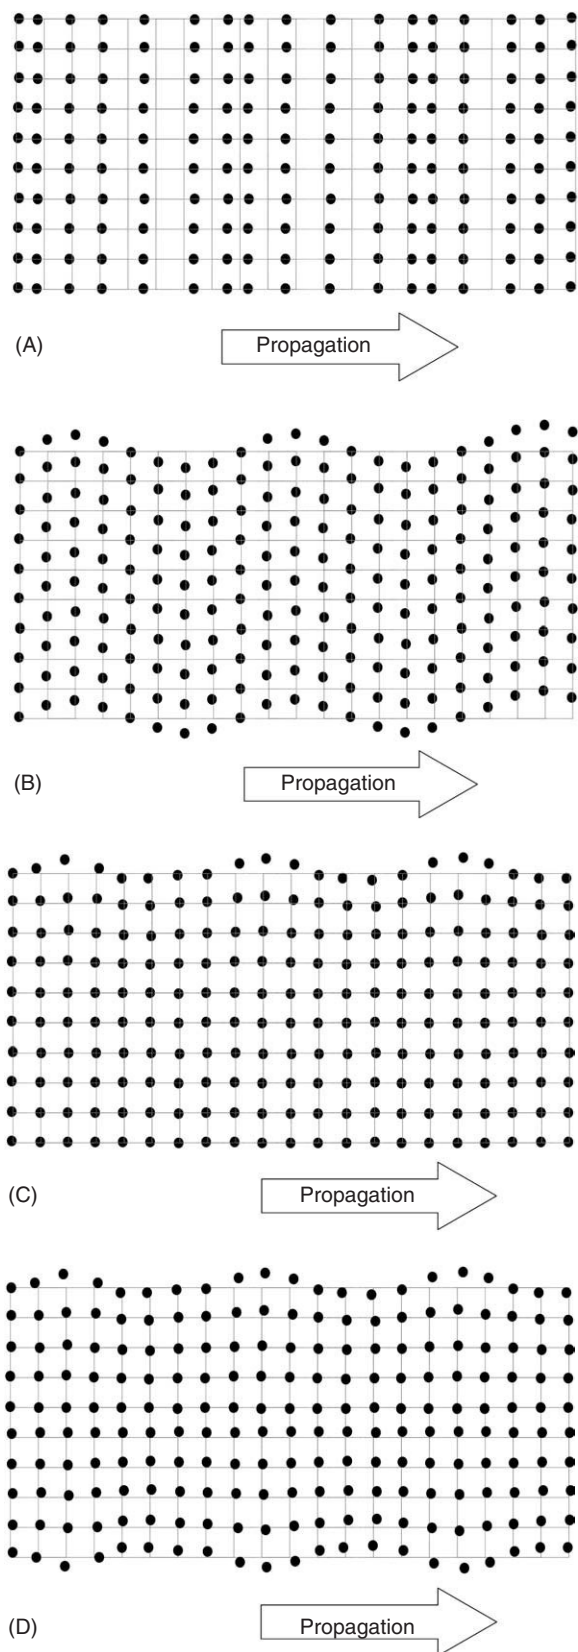

Acoustic waves are elastic waves that propagate through gases, liquids, and solids. In liquids and gases, longitudinal (compressional) waves are the only mode of propagation. The motion of the supporting medium is in the direction of propagation (Figure 2).

Bulk solids also support transverse (shear) waves. In these waves, the motion of the transmitting material is transverse to the direction of propagation.

In a bounded medium, such as thick metal plates, surface waves (Love waves and Rayleigh waves) occur. If the thickness of the plate is of the order of a few wavelengths, Lamb waves (plate waves) can propagate. These can be either symmetric or asymmetric. Generally, if the solid has moderate symmetry, unique waveforms can propagate, for example, tube waves.

The velocities of these propagation modes are different. Longitudinal waves are the fastest with about twice the velocity of transverse waves. The result is that the sensor detects a rather complex waveform. In process analytical applications this situation is somewhat relaxed due to these measurements being made in what is termed a 'diffuse field'. This arises for two reasons: (1) it is impossible to resolve individual acoustic events and (2) acoustic emission waves mix due to reflections from interfaces. This means that within a small area there is no real difference in the measured acoustic emission signal, no matter where the acoustic emission sensor is mounted or its orientation.

The main characteristics of an acoustic wave are its propagation mode ( $m$ ), velocity ( $v_m$ ), its amplitude ( $A$ ), and frequency (Table 1).

**Figure 2** Modes of acoustic propagation: (A) longitudinal or compressional wave; (B) transverse or shear wave; (C) surface or Rayleigh wave; and (D) plate or Lamb wave (symmetric mode).

**Table 1** Acoustic properties of some representative materials commonly found in the process environment

Material	Longitudinal velocity ( $m s^{-1}$ )	Transverse velocity ( $m s^{-1}$ )	Acoustic impedance ( $kg m^2 s^{-1}$ )
Aluminum (typical)	6320	3130	17.1
Steel (typical stainless)	5600	3120	46.5
Silica (fused)	5570	3520	14.5
PVC (hard)	2395	1060	3.35
Polyethylene (typical)	2667	No shear component	2.94
Motor oil (SAE20)	1740	—	1.51
Water (20°C)	1480	—	1.48
Ethanol	1180	—	0.93
Air	343	—	0.0004

The exact values of the quantities depend on the purity, method of production, and temperature.

The velocity of the wave is related to the density ( $\rho$ ) and the elastic constant ( $c_m$ ) of the medium through which it is propagating (in the equation shown below). The elastic constant is unique to the mode of propagation and to the material. For example, in liquids  $c_m$  is the adiabatic bulk modulus ( $B$ ):

$$v_m = \sqrt{\frac{c_m}{\rho}}$$

Acoustic impedance is an important parameter. When an acoustic wave passes from one medium to another, some of the energy is transmitted and some is reflected. The acoustic impedance controls the ratio of transmitted to reflected energy. In acoustic emission, monitoring the acoustic impedance explains the need for an acoustic coupling agent between the sensor and the surface on which it is mounted. Without this the detected signal will be very low, as most of the energy will be internally reflected at the wall.

The acoustic impedance of a material ( $Z_m$ ) is related, as is velocity, to density and elastic constant:

$$Z_m = \sqrt{\rho c_m}$$

The reflected intensity ( $I_r$ ) and the transmitted intensity ( $I_t$ ) (when the acoustic wave strikes an interface relates to acoustic impedance of both media ( $Z_1, Z_2$ )) are

$$I_r = \frac{(Z_1 - Z_2)^2}{(Z_1 + Z_2)^2}$$

$$I_t = \frac{4Z_1 Z_2}{(Z_1 + Z_2)^2}$$

## Instrumentation

The heart of an acoustic emission system is the sensor. The sensors are usually made of piezoelectric ceramic material such as PZT (lead zirconium titan-

ate). These materials are not naturally piezoelectric but are made piezoelectric by 'poling'. Poling consists of heating the material to a temperature in excess of its Curie temperature, applying a strong electrostatic field and then cooling it with the electrostatic field still applied. Above the Curie temperature the electrostatic dipoles become mobile, they align in the electrostatic field and on cooling lock into place. The Curie temperature for PZT ceramics is 328–365°C. After poling, when these materials are subjected to a physical stress the surfaces become charged. If they are set into vibration by an acoustic wave stress they produce an AC signal.

The Curie temperature represents the maximum temperature that a piezoelectric material can be exposed to. Above this temperature the electrostatic dipoles misalign and the piezoelectric properties are lost permanently.

The sensor consists of a small disc of piezoelectric coated on both sides with silver to make electrical contact. This disc is mounted in a metal can behind a ceramic faceplate for mechanical protection (Figure 3).

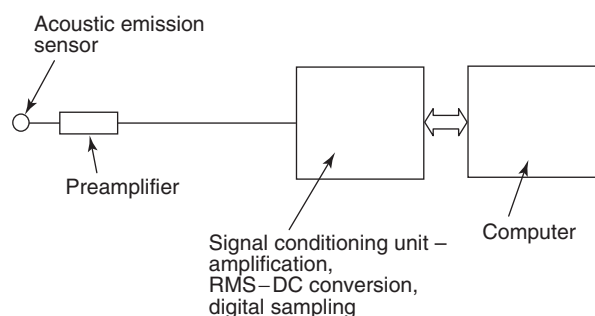

There are two main types of transducer. The most sensitive is the resonant transducer, which has its maximum sensitivity at the resonance frequency. Typical sensors have resonances in the range 70–600 kHz.

A second kind of transducer is the broadband sensor. In construction it is similar to a resonance sensor except that it has mechanical damping. These respond over range of several hundred kilohertz.

The sensor is attached to the outside wall of the vessel to be monitored. A small amount of acoustic coupling agent is placed between the faceplate of the sensor and the vessel surface. This provides impedance matching between the surface and the transducer, which greatly increases the sensitivity and reproducibility of the measurement. For temporary installations, grease or a proprietary acoustic coupling agent is used. For permanent installations an adhesive is used as it provides both acoustic coupling and mechanical strength.

**Figure 3** Acoustic emission sensor.

**Figure 4** Acoustic emission monitoring system.

A preamplifier is located close, usually within 2 m, to the acoustic sensor. This provides a low electrical impedance output so that the signal can be driven down a long coaxial cable to the signal-conditioning unit. Preamplifiers usually have a gain of 40 dB (Figure 4).

### RMS Conversion

The signal from a resonant transducer resembles an AM radio signal. It has a carrier wave, at the resonance frequency of the transducer, which is amplitude modulated by the process. The information about the process is in the modulation envelope. An RMS-to-DC (root mean square-to-direct current) converter is used to demodulate the signal. The output of this device is the amplitude of the envelope.

The envelope is digitally resampled at a frequency appropriate for the process. For instance, 50 Hz is a typical digital sampling rate for a fluid bed reactor.

In some simple applications it is sufficient to record the RMS signal. An example of this would be detecting fine material in a gas stream downstream of a cyclone.

### Direct Digitization

The acoustic emission signal may be directly digitized. This is useful if a broadband sensor is used or if

use is going to be made of digital signal processing (DSP) technology.

Sampling theory states that the signal must be sampled at twice the highest frequency present in the signal. If this criterion is not met then frequencies above the Nyquist frequency (half the digital-sampling rate) will be aliased; that is, they appear at spurious lower frequencies. To avoid this, very high sampling rates (10 MHz) must be employed.

DSP allows much of the signal processing to be performed in hardware. The DSP is able to calculate and output to its associated computer many parameters characterizing the signal such as RMS power, total energy in a given time, counts of pulses, and frequency analysis via hard coded FFT (fast Fourier transform).

### Counts/Ring Down Counts

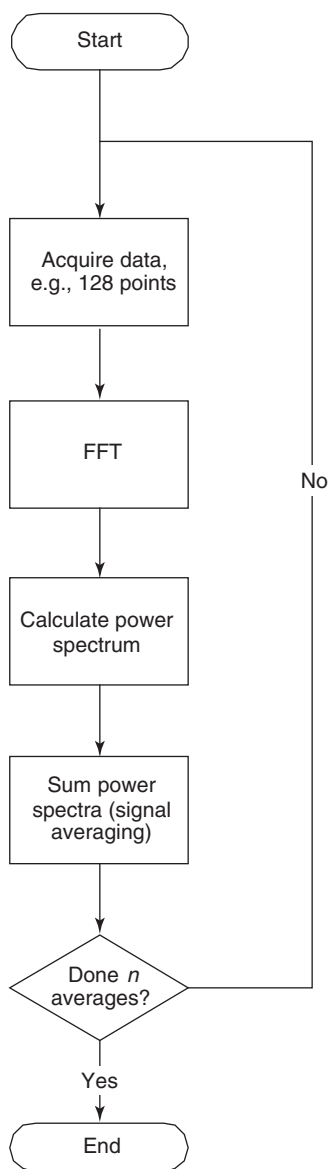

These measurements have been included for completeness. The origin of these parameters lies in the history of acoustic emission monitoring. These parameters are more significant in the realm of NDT than in process analysis. Counts are simply the number of acoustic emission bursts detected in a selected period. Ring down counts are an early attempt to measure the energy in a single burst. A voltage comparator is used to count how many detectable oscillations (threshold crossings) there are in burst. This provides a crude estimate of the energy.

### Data Analysis

Continuous acoustic emission is aperiodic, i.e., there is no start or stop to the signal. This means that it is not necessary to use signal-processing techniques that preserve phase. Power spectral analysis is therefore a useful technique. Because power spectra are coherent it is possible to gain a signal-to-noise improvement by averaging a number of power spectra. This spectrum may be of interest in its own right or used as signature for the state of the process. A scheme for calculating the power spectral estimate is given in (Figure 5). Other spectral analysis techniques, like the Gabor spectrogram, provide a good means of monitoring how the power frequency distribution varies with time (Figure 6).

Acoustic emission power spectra are similar in many respects to optical spectra and are amenable to chemometric processing (multivariate analysis). Principal component analysis, partial least squares (PLS), neural networks, and qualitative techniques such as SIMCA (soft independent modeling of class analogy; a pattern recognition technique) have been employed

**Figure 5** Power spectral analysis algorithm.

to analyze and empirically model acoustic emission producing processes.

## Applications

### Fluid Beds

Fluid bed technology is important in the oil, petrochemical, pharmaceutical, and food industries.

Catalytic cracking is an important process in the oil industry where petroleum vapor passes through a low-density bed of catalyst, which causes the heavier fractions to 'crack' producing lighter more valuable products.

**Figure 6** Gabor spectrogram representing a fingerprint of an entire high shear granulation process. The 'x-axis' represents time; the 'y-axis' represents frequency. The color represents intensity varying from black (low) through to yellow (high intensity).

In the petrochemicals industry they are used for producing polyolefins on a very large scale. The particles consist of growing polyolefin granules (polyethylene or polypropylene). The gas is the monomer ethylene or propylene.

Fluid beds are frequently used to produce granules or to dry particulate materials. These are of particular interest in the food and pharmaceutical industries.

In a fluidized bed, an upward current of gas suspends particles. The particles move upwards in the center of the bed and fall downwards, under gravity, at the walls. In dense beds a 'bubble phase' is often seen. These are pockets of gas moving upward through the bed. In the wake of these pockets is a stream of high-velocity particles. The bubbles are responsible for much of the mass transport of particles and are an important part of the mixing process. When bubbles grow too large they serve as conduits for gas by-pass thereby reducing gas-solid contact. In extreme cases when the bubble diameter approaches that of the vessel a phenomenon known as 'slugging' may develop. This lifts the material in the top sections of the bed causing loss of solid material and very poor efficiency.

Fluid beds produce large levels of acoustic emission. A resonant sensor, mounted on the outside wall of a fluid bed, senses the motion of the particles from their impact. Anything in the fluid bed, which changes the velocity, size, or hardness, brings about a change in the acoustic emission signals detected. The passing of bubbles through the bed causes a low-frequency modulation of the acoustic emission amplitude. As the bubble size changes the modulation frequency also changes. It is therefore easy to detect the onset of slugging behavior and to exercise a control measure.

Change in particle size and morphology influence the flow regimes within the bed and the acoustic

emission produced. Acoustic emission is a good indicator of the onset of bed disorders such as unwanted agglomeration of particles. In polyolefins production the product of the bed is a granule in the order of 200  $\mu\text{m}$  diameter. Under certain conditions these particles can agglomerate to form large lumps that disrupt the production process. Acoustic emission provides early indication that the nature of the bed is changing and that agglomerates are starting to form.

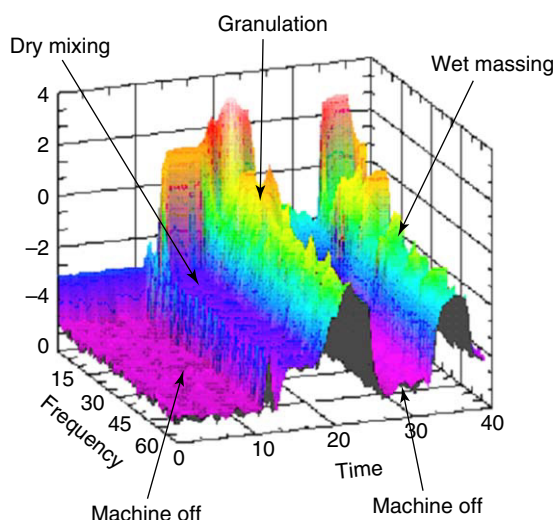

Pattern recognition (techniques such as SIMCA) performed on the acoustic emission spectrum has been used to detect deviations from normal operation and to predict endpoint conditions such as drying endpoint.

Powder transport lines can be considered as very lean fluidized beds. These are encountered in many industries; for instance, conveying powder-laden gases to cyclone separators. Here, acoustic emission proves to be a sensitive indicator for the presence of powders or liquid droplets, the detection of blockages, and as a semiquantitative indicator of the particulate mass flow.

### High-Shear Granulation

High-shear granulation is a process widely used in the pharmaceuticals industry. It is used to make granules ( $\sim 1000 \mu\text{m}$ ) from mixtures of much finer powders. The physical properties of the granules are very important as this affects their ability to be made into tablets. The powders need to be mixed to a very high degree of consistency, to ensure a uniform distribution of the active drug substance. The granules need to be freely flowing and have the right particle size distribution, density, and morphology for tablet making.

A high-shear granulator consists of a flat-bottomed mixing bowl and a multi-bladed impeller that rotates a very small distance above the bottom of the vessel. The first stage of the granulation process is dry mixing of the powder. After dry mixing, water and binder are sprayed into the vessel and the granulation process starts. Material is continuously mixed in the space above the impeller. The fine powder gradually agglomerates to form granules. At some point the addition of liquid is stopped and the material is left to complete the granulation. This process is known as 'wet massing'. The granulation process is stopped at a notional endpoint, i.e., when the particles have reached a satisfactory form for tablet making. Traditionally, the endpoint has been identified by visual inspection by an experienced operator. However, offline physical tests such as particle sizing, moisture content analysis, measurements of compressibility

**Figure 7** Change in power spectrum of RMS acoustic emission spectrum during high-shear granulation.

index (Carr's index), and flow characteristics are sometimes performed.

Under controlled conditions, these parameters may be quantitatively predicted from the acoustic emission spectrum using multivariate-modeling techniques such as PLS.

**Figure 7** shows the change in the RMS acoustic emission signal from a granulation process. Qualitatively it is easy to identify regions as static powder, dry blending, granulation, and wet massing. Dry mixing is characterized by a very flat spectrum (characteristic of truly random processes). As the liquid is added the powder starts to shear under the granulator blade. This produces intense broadband acoustic emission modulated by the passing of the impeller blades above the sensor. Similar levels of acoustic emission are seen during wet massing. As the material approaches the endpoint the acoustic emission signals tend to reduce in amplitude and stabilize.

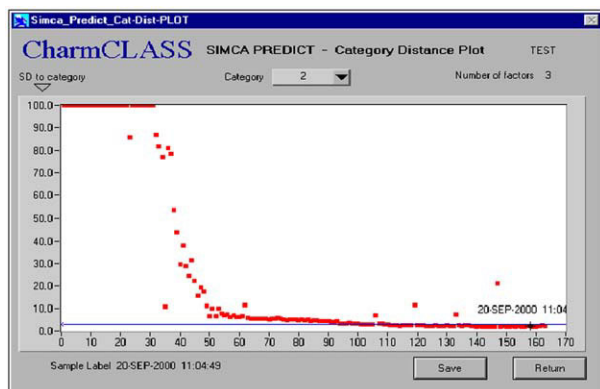

Pattern recognition techniques, like SIMCA, may be used to track the approach to endpoint by comparing the instantaneous acoustic emission spectrum with those obtained at the endpoint in previous production runs (**Figures 8 and 9**).

### Gas-Liquid Bubbles

Knowledge of bubble size distributions is important in gas-liquid systems, e.g., two-phase flow in pipelines, fermenters, and a variety of chemical reactors. In these cases, the acoustic emission extends from the audio region to  $\sim 50 \text{ kHz}$  and is usually detected by means of a submerged hydrophone.

**Figure 8** SIMCA modeling showing two multidimensional models (class 1 and class 2) made from acoustic emission signatures. In prediction mode the instantaneous acoustic emission signature (x) is compared to these models and a classification is made based on the distance the signature is from the centers of the models ( $d_1$ ,  $d_2$ ). The SIMCA distance is a measure of how well the instantaneous signal compares to the models. In this example the signature would be classified as belonging to class 1.

**Figure 9** SIMCA prediction output during high-shear granulation. The SIMCA distance reduces as the batch approaches its endpoint.

Each bubble has a number of possible modes of oscillation each producing a characteristic tone. For the air–water system the fundamental frequency of oscillation (Minnaert frequency)  $f_0$ , (where  $\gamma$  is the ratio of specific heats,  $s$  is the surface tension,  $P_\infty$  is the static pressure,  $R_0$  is the radius of the bubble,  $\rho$  is the density, and  $s$  is the surface tension) is given by:

$$f_0 = \left( \frac{3\gamma P_\infty}{\rho R_0^2} \right)^{1/2} / 2\pi - \left( \frac{2s}{\rho R_0^3} \right)^{1/2} / 2\pi$$

It is possible to model acoustic emission production from a population of bubbles of different sizes giving good correlation with physical measurements. The inverse problem has also been tackled; that is, the prediction of bubble size distributions from the acoustic emission spectrum. Good correlation (within 20% across the distribution) for bubble sizes from 0.2 to 10 mm has been obtained.

### Crystallization

Some chemical reactions produce acoustic emission directly. These require a phase change, i.e., liquid to gas, liquid to solid. Crystallization is a likely target for acoustic emission monitoring. There is some evidence that certain crystallization processes intrinsically produce acoustic emission. However, crystallization may be detected by the impact of the crystals on the walls of the reactor. As long as the fluid is well agitated acoustic emission gives a good estimate of the solid yield.

### Introduction

The use of analytical instrumentation for continuous online measurement of industrial process streams for real-time information gained popularity in the late 1950s and early 1960s. This information has met various demands, the most notable of which include process control, safety, waste reduction, environmental emission monitoring and control, and product quality assurance. With the application of computers and electronics to analyzer technology in recent decades, online analyzers have become even more sophisticated and widely used. In many instances, the application of online analysis has become a necessity for survival in the face of the economic pressures of globalization in chemical manufacturing.

Since process analysis has become so critical to the computers that control optimal operating conditions, the information from the field measurements, such as flow, temperature, pressure, level, compositions, etc. must be reliable and accurate. These measurements must receive adequate maintenance in order for the control to be successful. Compositional information from online analyzers provides more detailed information for process control than conventional pressure, temperature, and level data; thus, online analyzers justifiably require more attention than normal.

The real-time process analyzer is significantly different from conventional instrumental measurements in combining analytical chemistry with instrumentation. Typically, there is a sample transportation and conditioning system associated with the analysis, as well as some form of data presentation for human or automatic interface. It is also different from the laboratory analytical instrument. While laboratory analysis occurs within environmentally controlled conditions, the process analyzer is typically installed in a harsh environment and the analyses are taking place around the clock. Because of these unusual characteristics, the technicians responsible for analyzer maintenance must be thoroughly familiar with the entire analyzer system (analyzer as well as sample conditioning system). Analyzer technicians are typically well trained and highly skilled, and dedicated solely to analyzer system maintenance. Occasionally, analyzer technicians work side by side with laboratory technicians.

### Prerequisites of a Successful Maintenance Program

The successful analyzer maintenance program should meet two prerequisites: a well-engineered and properly installed analyzer system, and a well-structured maintenance organization and system to provide service and support. The analyzer system installation and engineering includes the selection of an appropriate analyzer and properly designed and installed sample transportation and conditioning system. The maintenance organization should be staffed with a supervisor and properly trained personnel to execute a well-structured maintenance program.

An analyzer system with improper engineering or installation will require excessive maintenance time and effort. Similarly, if there is no maintenance system in place when the analyzer system is installed, even a properly installed analyzer system will fail before long.

### Analyzer System Engineering

1. Economics analysis: The cost and benefit balance of analyzer system installation merits thorough consideration. The cost should include the initial cost of engineering, installation, personnel training, and the estimated cost of lifetime operation. The benefits should include the potential process improvement (such as better yield, less waste, safer operation, less pollution, etc.) resulting from analyzer usage. The cost and benefit balance should fall within the typical guidelines of the particular corporation (e.g., pay-back within 3 years).
2. Analyzer selection: The selection of the analyzer and the vendor also bears consideration. Some useful questions to ask include: Is the analyzer suited to its intended purpose (sensitivity, accuracy, interference, speed of analysis, etc.)? Does the analyzer have self-diagnostic capability to show signs of malfunctioning? Are service and parts readily available from the vendor? Is the vendor accountable for support for the lifetime of the analyzer?
3. The respective locations of the sample system and analyzer: The sample system should be well suited to the intended analysis. The representative sample must be taken where it will give the most insight of the process, and sample transportation must be timely so that the analysis can be used for real-time process control. Sample return should be considered as well if the sample would create any environmental, health, or safety problems. The analyzer must be well

protected from the weather, and access should be convenient and reasonably comfortable for maintenance technicians. The sample system should be designed so that its function can be safely and easily monitored regularly. Critical operating parameters, such as temperature and flow, should be monitored at the control room computer. The system design must include a safe means for isolating the analyzer and sample system from the process for service so that not to interfere the production.

4. Tools, operating manuals, spare parts, and training: Any special tools, manuals, and training for each analyzer and the sample system must be provided. Any spare parts recommended by the manufacturer should be on hand. Training can be done several different ways: offsite, onsite, or on the job training. Also, the freedom of computer-based training allows training to be taken at any time and individual pace.

### Maintenance Organization

Analyzer system design, engineering, installation, and long-term operation involve many disciplines: analytical and physical chemistry, electrical, mechanical, chemical and project engineering, and management. Therefore, it is not always obvious where to place the maintenance organization. Sometimes, analyzer maintenance is an afterthought because of the immediate need to improve the process. After the analyzer has been installed, the maintenance of it is often assigned to whatever group happens to make the most sense under these particular circumstances.

Depending on the size of the plant, the number of analyzers, the culture of the location, and, to some extent, precedents in maintenance practice, the analyzer maintenance organization may be of any variety. Smaller plants may have a few analyzers that require only one person to maintain. A large plant may need to have a well-structured and staffed department to maintain the analyzers throughout the plant. Some plants may choose to have some analyzer technicians assigned to a certain production area, while others may assign technicians based on their skill levels. The analyzer maintenance organization may be localized or centralized.

The maintenance organization could be in one of many areas, including the instrument shop, engineering department, central laboratory, process control group, production area, or process research department.

Generally, a well-structured maintenance organization should consist of the following elements:

1. The supervisor: Functions as a central figure to coordinate and manage all the maintenance activities for the whole organization. This person should be intimately familiar with all the analyzers and the sample systems installed in the plant, and should have a general knowledge of analyzer technology. The supervisor should be able to answer any technical question from the technicians, and also be motivating to the technicians. The supervisor should be fully aware of each technician's skills and ability, and should be responsible to arrange proper technician training. The supervisor should be the single point of contact for customers regarding any analyzer related issue.
2. Technicians and training: The number of analyzers assigned to each technician depends on the complexity of the analyzer and, sometimes, on the importance of the analyzer and the skill level of the technicians. The technicians should have basic computer skills and familiarity with basic statistics. Technician training should be an on-going activity. At least 10–20% of working hours should be allocated to training.
3. Spare parts inventory: There should be a well-stocked and organized inventory of spare parts. Part of the maintenance organization should be dedicated to replenishing missing parts and refreshing the list periodically.
4. Tools and equipment: The analyzer group should be equipped with essential tools and basic equipment, such as computers, multimeters, scopes, etc.
5. Accountability: Accountability should be assigned to the supervisor and technicians for their assigned duties.
6. Vendors and contractors: The analyzer group should have both an updated vendor service contact list as well as the local analyzer service contractor list for external service and training support.
7. Close communication with customers/users: The maintenance organization should have periodic communication with the users to ensure that the analyzer data are being used correctly. The users should be notified when the analyzer is being serviced, and the maintenance group should be notified when the data are suspicious or erroneous.

### Analyzer System Maintenance

After the analyzer and the sample conditioning system are installed, commissioned, and turned over to the maintenance organization, it is time for the maintenance to ward off problems as long as possible and at minimal cost. The successful maintenance program can be broken down into these essential elements:

1. Technicians' knowledge: Analyzer technicians should have a comprehensive understanding of the

functions of the analyzer, sample system construction, and safe operation. They should also understand the purpose of the analyzer, both in production as well as its impact to the bottom line for the corporation. They need to understand and be aware of their contribution to successful analyzer operation.

2. Maintenance modes: The two modes of maintenance are reactive and proactive. A strictly reactive maintenance program has no maintenance plan, does not monitor the analyzer and the sample system regularly, and only performs maintenance when the system fails. Reactive maintenance is ineffective and inefficient, trading the cost of regular maintenance for the usually greater cost of repairing broken equipment. Proactive maintenance has a structured schedule and procedure on each analyzer system for the assigned technicians to perform. Such maintenance could range from a routine checklist to a complete overhaul of the analyzer or the sample system. This kind of maintenance program takes time to develop because each analyzer system installation and application is unique. A proven maintenance program for an analyzer system on one process may not work as well for the same analyzer system at another process, even if they are in the same facility. Statistical process control technique and a quality assurance program will help develop a proactive maintenance program.

3. Statistic process control: Dr. W. Edwards Deming revolutionized the manufacturing process by applying statistics to a simple control chart concept that can be used to tighten the manufacturing process and improve quality. This technique should be used to maintain the analyzer system. Data should be collected to construct control charts, and maintenance decisions regarding the analyzer system should be based on the control charts. For example, data collected from repeated analyses of a calibration standard are used to construct the control charts. The control charts contain the upper and lower control limits and the range. If subsequent periodic analysis of the same calibration produces a result that falls outside the control limits, this indicates a problem in the system. The maintenance plan should be able to identify the cause of the problem and resolve it.

4. Quality assurance (QA) program for analyzer and sample system: This is closely related to the control chart concept. The capability of the analyzer (e.g., accuracy, reproducibility, etc.) and the sample system (e.g., temperature, pressure, flow, etc.) should be established as soon as possible after installation. The control charts (mentioned above) of statistical process control technique should indicate the capabilities of the analyzer system. The analyzer should be checked against a calibration

standard and the operating parameters for the sample system (such as flow, temperature, etc.) should be monitored and documented periodically. These records are helpful to modify the maintenance schedule for the future. For example, if a flow check on the sample system remains the same for a month with daily checks, the maintenance schedule may be extended to once a month at the next revision. On the other hand, if pressure measurements of the sample system begin to decrease at the end of a week, the system may need to be cleaned more frequently. QA data can convert routine maintenance to preventive, and even to predictive, maintenance. The more QA data are collected, the better the system can become.

5. Documentation: Operating manuals, service procedures and schedule, cost and benefit analysis, analyzer history, service records (based on control charts), drawings, etc. should be well documented and organized.

6. Data network: With networking capability, analyzer data can often be viewed and archived on an internal data network. This is very convenient for the analyzer technicians and engineers to view the analyzer data at their offices and to analyze data along with other operating parameters for any correlation.

7. Maintain spare parts inventory: Part of the technicians' regular duty is to maintain adequate inventory of consumable parts, such as filter elements, calibration standards, etc. and critical parts for the analyzer and the sample systems, such as gas chromatography columns, special fittings and valves, etc. For a very critical operation, a redundant analyzer may be justifiable as a hot standby item.

8. Ongoing training: Technicians' skills and knowledge should be periodically reviewed and assessed. Refresher and new training for new installation or new personnel should be ongoing to maintain the adequate competency. Attending analyzer conferences should be encouraged, especially for the supervisor, in order to keep abreast with the latest analyzer technology.

9. Maintain regular communication with customers, lab, and analyzer vendors: The users (customers) should be regularly communicated for their feedback of the service provided. It is a good idea for the analyzer supervisor to attend the regular production meetings in order to keep updated with the level of support on the analyzer systems. The analyzer group should also maintain close communication with the vendors for new product introduction and training opportunity. The analyzer technicians should work closely with the lab personnel for mutual support of the analytical efforts.

10. Replace, upgrade, or remove analyzers: All the analyzer installations should be periodically reviewed for its operability and cost effectiveness. This should be performed with the production personnel to determine if the analyzer needs to be replaced, upgraded, or removed if it no longer serves the purpose.

## Analyzer System Training

As mentioned earlier, the analyzer system is typically composed of an analyzer, the sample transportation, and conditioning system. Maintenance activities should include all parts of the system in order to be successful. Thus, the training should be on all these aspects of the system. The technicians should be responsible and accountable for all the elements associated with the analyzer system. A well-calibrated analyzer without a representative process sample to analyze is useless. Wrong data is worse than no data. The technicians should be equipped with the proper knowledge and skills from the training programs.

The training can be achieved by several different ways: Classroom training, onsite or offsite training, computer-based training, hands-on training, on-the-job training and the latest, web-based training.

Training programs are usually categorized into the following areas:

1. Analyzer training: Subjects should include: how the analyzer works, includes some basic chemistry, physics, and electronics; some basic statistics knowledge, such as of standard deviation, is very helpful. The technicians should be familiar with the analyzer capability, such as the sensitivity, response time, analytical accuracy, and repeatability. The QA program and troubleshooting procedures should also be included.
2. Sample system training: The technicians should be familiar with the entire sample transportation and conditioning system. Several key questions should be asked: Where does the sample come from and return? Under what specific operating parameters, such as temperature, pressure, flow rate, should the sample system be operated? How to monitor the system performance and how to isolate the sample system from process for offline service? How to safely take a representative sample for offline analysis? With a QA program and use of the statistical process control, the technicians should be trained to determine when to service the sample system, such as water wash to clear the sample line; and when to replace some parts, such as a dirty filter.
3. Computer skills training: The analyzer technicians should have some basic computer skills in

word processing, spreadsheet, and file and data management. The technicians should be expected to write some simple reports on occasions for documentation purpose. Some commercially available or customized maintenance software can be helpful in keeping the analyzer and maintenance records. This maintenance software may also contain comprehensive manuals and troubleshooting guides for all the analyzers. There are companies that, for a fee, will provide the service to populate the data in the maintenance software for the customers and conduct user training. For a large facility with many installed analyzers, this may be a beneficial investment.

4. Conferences, research consortiums: To keep up-to-date with the new technology, the analyzer personnel should attend conferences on process analyzers, such as the annual meetings of International Forum on Process Analytical Chemistry (IFPAC) and Instrument Society of America Analysis Division (ISA A/D). Research consortiums (membership required), such as Center for Process Analytical Chemistry (CPAC) at University of Washington and Measurement and Control Engineering Center (MCEC) at University of Tennessee are the well-known centers in the USA devoted to the process analysis research and applications. Sponsoring members are usually exposed to cutting edge technologies in the process analysis areas. These conferences and research consortiums often sponsor useful training programs in the analyzer areas in conjunction with their biannual meetings.

## Analyzer System Reliability

### Definition of Reliability

Reliability is the probability that an equipment can perform continuously without failure for a specific period of time. Reliability can be also the capability of an equipment continuously to perform its intended functions. Normally, reliability is measured by mean time between repairs (MTBR). MTBR is equivalent to the total equipment or instrument downtime in a given period, divided by the number of failures in that period. Reliability engineering can be defined as a staff function. The prime responsibility is to ensure that maintenance techniques are applied effectively, that equipment is designed and modified to improve maintainability and operability, that ongoing maintenance technical problems are investigated, and appropriate corrective and improvement actions are taken. Analyzers and sample systems reliability depends on an effective design, good operation, and good maintenance practices.

### **Analyzer Reliability Vision**

In order to achieve operational consistency, process must be controllable and operated properly. Analyzers for a chemical process serve as a powerful tool to help process engineers and operators to effectively do their jobs. In the following examples, reliable analyzers are definitely required for these tasks:

1. For troubleshooting process upsets: Production personnel monitor and control the process in a consistent manner to produce quality products. When process upsets occur, there must be sufficient confidence in the analyzer data so that quick analysis of the 'out of control' situation is made and the appropriate corrective actions are undertaken.
2. For process improvement: Technical support will have the reliable process data to analyze production efficiency and formulate optimization strategies to improve process performance.
3. For process optimization research: Accurate and tight control will enable the execution of well-designed experiments in a controlled environment and provide data that can be used with confidence in process optimization.

### **Analyzer Reliability Strategy**

A reliability strategy is composed of the following programs:

1. Training program: A good maintenance analyzer facility will develop its own training program based upon the analyzers installed in the plant or facility. The analyzers training program will need clear, concise training objectives written that are based on verified data. A formalized evaluation process should be performed to determine the success of the training program. On-the-job training should be considered, with evaluation/certification of the trainee.
2. Develop 'Top Ten' bad actors list: The purpose of the bad actors list is to establish the analyzers within the facility that shall receive priority for resource allocation determination. These resources include preventive maintenance, spare parts, reliability study, and necessary training for technicians and operators. The 'Top Ten' bad actors list ranks the importance based on the following three categories:
  - frequency,
  - maintenance cost, and
  - safety/environment impact on business (productivity and quality). This list should be generated periodically for discussion with the production

personnel to take proper action to address the bad actors.

3. Elaborate or revise the maintenance procedures and preventive maintenance: We rely on maintenance procedures as a tool in achieving consistent performance. They set a right way based on experience and manufacturers advice and allow any qualified person to perform the maintenance work as expected. The maintenance procedures will define all requirements covering maintenance of the analyzers, including tracking performance, and alerting to overdue maintenance. It's a common assumption that certain individuals will always do a particular task and they will remember exactly the best way to do it every time, every day. We want reliable performance from our analyzers, and consistently doing the correct things leads to reliable performance.

4. Analyzers database implementation: Normally the data provided by the computerized maintenance management systems (CMMS) are not sufficient to provide the information needed to make the right decisions regarding improving analyzers reliability. The combination of the CMMS and an analyzer database provides a very powerful tool. Today, there are several commercial instrument database software available in the market. Alternatively, an analyzer database can be developed in-house using common database software such as Microsoft Access. An analyzer database should contain the following basic information:

- general information (manufacturer, model/serial number, applications, etc.);
- parts replaced over a period of time;
- calibration information (accuracy, deviation, range, as found/as left);
- name of the technician;
- date; and
- maintenance procedures.

5. Spare Parts evaluation: The analyzer maintenance expeditor should maintain close ties with the plant warehouse and the purchasing department to optimize parts availability and its location. Spare parts should be readily available when needed. Vendor information should be used as a guide to determine the parts to be included in stores. We have to be careful to avoid over-stocking of parts to control the cost. If the expensive parts can be readily obtained from vendors in a timely manner, then it need not be in the warehouse.

6. Metrics to evaluate the results: The metrics should be visible, understood, and used by the people involved in the process to improve analyzers reliability. The metrics will show how well the strategy to

improve analyzers reliability is working. These data should be reviewed periodically to improve the reliability and reduce the cost. Below are some metrics that can be used to measure analyzer performance:

- maintenance cost (labor and materials);
- MTBR: mean time between repairs;
- uptime: defined as the time that an item of equipment is in service and operating; and
- production loss caused by analyzer malfunction.

## Introduction

Knowledge of the physiological state of cells and the physicochemical conditions of the bioreactor environment is required for an optimal bioprocess control. The analysis of bioprocesses is based on physical, chemical, and biological parameters. A selection of offline and online parameters, which are used for the analysis of bioprocesses, is shown in **Table 1**.

A comprehensive understanding of the physiology of industrially relevant prokaryotic or eukaryotic cells during bioprocesses is mandatory for a successful strain and process optimization. The physiological status of the cells during a bioprocess can be measured indirectly by analyses of external variables outside the cells or directly by measuring cellular components inside the cells. New molecular analytical methods allow the determination of detailed biomolecular parameters of the production cells. Physicochemical separation techniques like chromatography or gel electrophoresis allow an accurate separation of molecular components of cells. Furthermore, the analysis of key metabolites gives valuable information on the cellular physiology of the cells.

Gene expression activities of cells can be determined primarily by their mRNA and finally by their protein pattern. The proteomics approach, which is based either on electrophoretic separation of the cellular proteins (proteome) and their identification by mass spectrometry (MS) or on protein chips, allows a visualization of the final products of the gene expression activity of the cells, and thus reflects rather closely their *in vivo* physiological state. The proteome analysis technique, however, has some limitations and does not allow a determination of the expression of all process relevant genes. In this respect, the DNA array technology represents a further quantum jump in the molecular physiological state analysis. DNA arrays allow a faster analysis of the expression of process-relevant genes at a certain time during a bioprocess. In comparison to proteins, mRNA levels reflect changes in the bioprocess performance at a rather early stage. However, the combination of proteome and transcriptome analysis allows a nearly comprehensive view on the physiological state of the cells and may contribute to evaluation of process-related bottlenecks. The integration of different analytical data and the understanding of complex cellular regulatory networks offer new perspectives in the optimization and control of bioprocesses. In this respect, expert systems and models for control are very helpful tools to maintain the process at optimal conditions.

improve analyzers reliability is working. These data should be reviewed periodically to improve the reliability and reduce the cost. Below are some metrics that can be used to measure analyzer performance:

- maintenance cost (labor and materials);
- MTBR: mean time between repairs;
- uptime: defined as the time that an item of equipment is in service and operating; and
- production loss caused by analyzer malfunction.

## Introduction

Knowledge of the physiological state of cells and the physicochemical conditions of the bioreactor environment is required for an optimal bioprocess control. The analysis of bioprocesses is based on physical, chemical, and biological parameters. A selection of offline and online parameters, which are used for the analysis of bioprocesses, is shown in **Table 1**.

A comprehensive understanding of the physiology of industrially relevant prokaryotic or eukaryotic cells during bioprocesses is mandatory for a successful strain and process optimization. The physiological status of the cells during a bioprocess can be measured indirectly by analyses of external variables outside the cells or directly by measuring cellular components inside the cells. New molecular analytical methods allow the determination of detailed biomolecular parameters of the production cells. Physicochemical separation techniques like chromatography or gel electrophoresis allow an accurate separation of molecular components of cells. Furthermore, the analysis of key metabolites gives valuable information on the cellular physiology of the cells.

Gene expression activities of cells can be determined primarily by their mRNA and finally by their protein pattern. The proteomics approach, which is based either on electrophoretic separation of the cellular proteins (proteome) and their identification by mass spectrometry (MS) or on protein chips, allows a visualization of the final products of the gene expression activity of the cells, and thus reflects rather closely their *in vivo* physiological state. The proteome analysis technique, however, has some limitations and does not allow a determination of the expression of all process relevant genes. In this respect, the DNA array technology represents a further quantum jump in the molecular physiological state analysis. DNA arrays allow a faster analysis of the expression of process-relevant genes at a certain time during a bioprocess. In comparison to proteins, mRNA levels reflect changes in the bioprocess performance at a rather early stage. However, the combination of proteome and transcriptome analysis allows a nearly comprehensive view on the physiological state of the cells and may contribute to evaluation of process-related bottlenecks. The integration of different analytical data and the understanding of complex cellular regulatory networks offer new perspectives in the optimization and control of bioprocesses. In this respect, expert systems and models for control are very helpful tools to maintain the process at optimal conditions.

**Table 1** Online and offline parameters for the monitoring of the physiology of cells during bioprocesses

Parameters	Analytes	Measuring device/methods
<i>Online</i>		
Growth, cell density	Cell population, broth	Spectrophotometry
pH	Broth	pH electrode
Metabolism	Metabolites	HPLC
Respiration	$pO_2$ level	$pO_2$ electrode
Exhaust gas composition	$CO_2$ , $O_2$	Gas analyzers, MS
<i>Offline</i>		
Cell viability/population analysis	Single cells	Flow cytometry, FISH, plating, microscopy
Energetic pool	Nucleotides	HPLC, enzymatic test
Gene expression	mRNAs	Real-time RT-PCR, DNA chips, Northern blot
	Proteins	2D-PAGE/MS, protein chips, enzymatic analyses, immunologic methods
Metabolism	Metabolites	NMR, TLC, HPLC, enzymatic analyses
Stress	Free amino acids	HPLC
	Stress specific mRNAs or proteins	Real-time RT-PCR DNA- or protein-chips, proteome analysis
Medium components	Carbohydrates, ammonia/nitrogen	Enzymatic, HPLC (Micro)-Kjeldahl, ion-sensitive electrode
	Phosphate	Chemical analysis
	Total protein	Chemical analysis

FISH, fluorescence *in situ* hybridization; HPLC, high-performance liquid chromatography; MS, mass spectrometry; NMR, nuclear magnetic resonance; PCR, polymerase chain reaction; RT, reverse transcription; TLC, thin-layer chromatography; 2D-PAGE, two-dimensional polyacrylamide gel electrophoresis.

## Analytical Methods for Bioprocess Monitoring

### Online Parameters

State-of-the-art bioreactors allow the online detection and control of a number of process variables. These online variables can be used to calculate culture-specific parameters, which characterize the cell's activity and the growth state. Generally, pH, dissolved oxygen tension ( $pO_2$ ), and temperature are measured continuously. In connection to other online data, such as level or fermenter weight, pressure, temperature of cooling water circuit, stirrer power input, and volume of additives, these measures can be used to evaluate the growth state. Much additional information can be obtained by outgas analysis (infrared for  $CO_2$ , paramagnetic for  $O_2$ , or other principles such as electroacoustic methods and MS). Volumetric rates, e.g., for oxygen consumption,  $CO_2$  formation, and heat production can be calculated. From these volumetric rates, specific rates (e.g., specific growth rate, specific substrate uptake rate) and yield parameters (e.g.,  $Y_O/S$ , RQ-value) can be derived that contain a high information content.

Methods for detection of biomass can be divided into direct and indirect methods (Table 2). Most online probes for direct monitoring of cell mass are based on optical principles, including light absorbance, light scattering, and fluorescence. Although such sensors may work well in specific cases, often

**Table 2** Methods for online analysis of biomass during fermentation processes

Direct	Electrical	Conductivity Capacitance
	Optical	Fluorescence Light absorbance Light scattering Real-time imaging
Indirect	Acoustic resonance densitometry Nuclear magnetic resonance spectroscopy	
	Oxygen uptake rate	
	Carbon dioxide evolution rate	
	ATP-production rate	
	NAD sensor	Fluorescence
	Heat production	Calorimetry
	Stirrer power input	
	Redox level	
	pH value/base addition	
	GFP	Fluorescence

GFP, green fluorescent protein; NAD, nicotinic acid adenine dinucleotide; ATP, adenosine tri-phosphate.

the influence of medium components disturbs the measurement. Furthermore, most of these sensors cannot be used in high-cell-density cultivations. Alternatively, sensors with electrical principles, such as capacitance and conductivity, have been developed. These sensors can be used at high cell densities and even in densely packed bioreactors like fixed-bed systems.

Indirect methods are based on the measurement of cellular activities and mostly detect viable cells. These methods often make use of standard online sensors, such as outgas analysis, pH, power input to stirrer, temperature input, or specific probes such as redox electrode or fluorescence sensors for the detection of NADH or green fluorescent protein (GFP), and subsequently apply calculations or simple models for the determination of biomass.

Generally, care must be taken in calibration of the online biomass sensors. The conditions of their use have to be standardized, as medium components, particles, gas bubbles, etc. may disturb the signal.

**Electronic noses** The so-called electronic noses consist of chemical gas sensors that are able to monitor changes in the offgas composition of fermentation processes. The different sensors of electronic noses are based on conductive polymers (CP), metal oxide semiconductors (MOS), metal oxide semiconductor field effect transistors (MOSFET), or quartz crystal microbalance (QCM). CP-based sensors use the electrochemical properties of polymers like polypyrrole or polyindole. The absorbance of selected molecules of the off-gas into the polymer film causes changes in the sensors conductivity. MOS sensors possess an electrochemically active surface of metal oxides like tin oxide or copper oxide. The sensitivity

of this type of gas sensors toward different inorganic (e.g., hydrogen, carbon monoxide, ammonia, hydrogen sulfide, nitrogen oxide, or sulfurous compounds) or organic compounds (e.g., alcohols and hydrocarbons) of the off-gas is modulated by the oxide composition, the amount of trace elements (e.g., palladium, gold or rhodium), and the temperature, which ranges from 100°C to 400°C. A MOSFET sensor is based on thin catalytic metal films covering a silicon oxide field effect transistor. The catalytic decomposition of organic and inorganic compounds on the surface causes shifts in the capacitance of the semiconductor device of this sensor. QCM sensors are able to measure the physical mass of a bound analyte. This is reached by determination of changes in the frequency of a quartz crystal by binding of the analyte to the sensor surface.

### Offline Parameters

**Medium components** The analysis of components in the cultivation medium during bioprocesses requires sampling procedures that consider the appropriate rate constants of their consumption or synthesis. A selection of different sampling procedures for the analysis of cellular components or medium compounds during fermentation processes is shown in Table 3.

**Table 3** Methods for sampling of cellular components or compounds in the fermentation medium

Example	Sampling	Quenching/inactivation		Extraction	Stabilization/storage
		Physical	Chemical		
Glycolysis intermediates	By overpressure (bioreactor) or underpressure (sampling vial)	Low temperature (–20 to –70°C)	Methanol	Perchloric acid	–70°C
mRNAs			Phenol/ethanol		RNase inhibitor, –70°C
Nucleotides			Perchloric acid	Repeated freeze/thaw cycles	–70°C after titration to pH 7
Nucleotides			Formaldehyde	Basic (KOH)	–70°C
Isotopomer distributions in intracellular proteinogenic amino acids		Low temperature, 0°C			–70°C
Proteins, 2D-PAGE			Chloramphenicol/ NaN <sub>3</sub>		–70°C
Medium components		Filtration through 0.2 or 0.4 µm filters			–0°C
Medium components		Centrifugation			–70°C
Medium components (glucose, acetate)		Centrifugation	Perchloric acid		–70°C after titration to pH 7

KOH, potassium hydroxide; 2D-PAGE, two-dimensional polyacrylamide gel electrophoresis.

Sampling techniques are challenging for medium components with a high rate constant and low concentration especially at high cell densities. Examples of medium components are carbon compounds (e.g., glucose, acetate), nitrogen compounds (e.g., ammonia,  $\text{NO}_2$ ), extracellular metabolites (e.g., amino acids), and signal compounds (e.g., extracellular cAMP). For medium sampling filtration techniques including dialysis through filters and bypass modules are normally used. Thereby filter clogging, binding of the analytes to the filter, and residual target-transforming activities have to be kept in mind and should be critically evaluated in each case.

Glucose is the most favored carbon and energy source of many industrial microorganisms and thus one of the most frequently used nutrients in biotechnological processes. Many processes apply the fed-batch technology, which is used to reach high cell densities as a basis for high product yield by the continuous growth-limiting addition of concentrated carbon substrate solutions. This technique combines the advantages of avoiding substrate inhibition and the production of unwanted metabolic side products, thereby allowing bioprocesses with high cell densities and without oxygen limitation. However, by definition the concentration of the limiting substrate is in the order of magnitude of the saturation constant  $K_s$ . For glucose, the saturation constant is in the  $\text{mg l}^{-1}$  range, but the glucose uptake rate of a culture at a higher cell density is in the order of  $10 \text{ mg l}^{-1} \text{ s}^{-1}$ . Therefore, the detection of actual glucose concentrations in glucose-limited fed-batch cultivations is a challenge and demands a fast inactivation of further cellular metabolic activities. Preferred methods are direct sampling of the cell broth in ice-cold quenching solutions, such as perchloric acid or methanol, by taking advantage of the overpressure in the fermenter, or sampling with a concentric double lumen catheter with inactivating liquid in the outer tube and inactivation at the point where the cell broth is sucked into the inner catheter. Although the latter method has been successfully used in line with a dialysis module as an online sampling tool in fermentations and for blood sugar analysis in the human body, the method is not widely used for bioprocess analyses due to the missing sterility barrier. Alternatively, syringes (monovettes) with underpressure, as they are also used for blood sampling, have been applied successfully for offline sampling in combination with cooling for bioprocess analyses. It must be taken into account that inactivation with quenching solutions can result in leakage of cellular compounds to the medium, which may be specific to the cultured organism.

The analysis of glucose and other sugars is generally performed by high-performance liquid

chromatography (HPLC) or by enzymatic assays. Enzyme electrodes have also been tested. They, however, cannot be used inside a bioreactor due to their limited heat stability. However, several flow injection systems (flow injection analysis, FIA) have been realized and are commercialized today. They allow a detection of the analyte with a short time delay of seconds to minutes with a sampling interval down to one sample per minute.

A specific problem for the use of such medium analyses in the control of a bioprocess can be caused by insufficient mixing of the bioreactor environment. Local zones of high or low nutrient concentrations or varying oxygen availability can produce gradients in the concentration of the analyte. It has been demonstrated that in large-scale fed-batch processes the concentration of the limiting substrate fluctuates due to slow mixing of the feed solution. Feed solutions are usually applied as highly concentrated and viscous solutions to minimize the dilution effects. The limiting substrate concentration in a fed-batch fermentation process depends on the sugar uptake kinetics, but is generally by the order of 10 000 smaller than the feed concentration. This creates a dynamic situation in large fed-batch bioprocesses. Cells repeatedly pass close to the feed point and are exposed, for a short time, to a much higher sugar concentration than the mean concentration in the reactor. A rapid utilization of the sugar and concomitant local oxygen limitation is expected at high cell densities. Furthermore, many microorganisms respond by overflow metabolism when exposed to glucose concentrations above a critical level. Furthermore, local oxygen limitations in the bioreactor environment create specific anaerobic conditions and provoke concomitant stress responses.

A nitrogen balance by monitoring inorganic and organic nitrogen may help to better understand the metabolic activities in a bioprocess. In dependence on the microorganism applied, microbial media may contain nitrogen in different oxidation states as nitrate, nitrite, ammonia, and organic nitrogen. Organic nitrogen occurs in proteins, peptides, amino sugars, nucleic acids, and urea. Ammonia and nitrate are alternatively used as inorganic nitrogen sources, whereas organic nitrogen is contained in complex media and in products of microbial activities including the biomass. Analytically, ammonia and organic nitrogen can be determined together using the Kjeldahl method or by ion-sensitive electrodes. Generally, for an accurate assessment of total nitrogen, all of the various nitrogen forms are separately measured and then the results are summarized. Consequently, analysis for total nitrogen is a time-consuming and difficult procedure. Most of the methods are wet

chemical methods including ultraviolet/visible spectroscopy requiring extensive sample preparation with several digestions and/or titration steps. New methods for the determination of total nitrogen, which simplify and speed up the analysis, are based on either gas chromatography with a flame ionization detector for gaseous nitrogen compounds or on chemiluminescence for liquid and solid samples with prior combustion to nitrogen monoxide and nitrogen dioxide and following reaction with ozone to form an excited state of nitrogen dioxide. Upon returning to ground state, light energy is emitted. Total nitrogen is measured using a chemiluminescence detector.

Phosphate is analyzed spectrophotometrically by a chemical reaction with ammonia molybdenum and iron sulfate or by ion chromatography.

**General cell parameters** Traditionally, a large number of methods has been applied to analyze general cell parameters in bioprocesses such as gravimetry (cell dry weight, cell wet weight), volumetry (sedimentation volume), optical methods (e.g., light absorbance in the range of 500–650 nm), visualization in microscopic counting chambers (cell count), or growth-based methods (replica plating or spreading out). Whereas all these methods have in common to consider the biomass as a unit, a number of modern methods aims for the analysis of subpopulations to get information about the variability in a bioprocess. In the analysis of subpopulations flow cytometry has been a breakthrough although the size of bacteria is still at the lower end of the technology. Combination with fluorescing labeling compounds makes flow cytometry a powerful analytical method. This method has the major advantage of being able to combine single cell analysis with a high sample throughput. Current flow cytometers allow the analysis of  $\sim 10^4$  cells per second and thus give statistically ensured data on the properties of the cells during different stages of a bioprocess. Cellular components or the integrity of cells can be analyzed by applying distinct staining procedures with fluorescing compounds that are available in a large number. The complexity of labeling protocols is the reason why this technique has not been performed online so far. The cells are analyzed cell by cell in a flowthrough chamber, where each cell is determined by a light source, usually a laser beam, and an appropriate detection unit, which measures the scattered and the fluorescence light emitted by the distinct fluorescence dyes. By this approach not only cell number, size, and shape can be explored but also the viability of cells, cell wall integrity, internal pH, inclusion bodies, storage material, and DNA, RNA, or protein content. The flow

cytometry analysis gives valuable information on the physiological state of the cells and thus on the performance of the whole bioprocess. Flow cytometry has a good potential to be combined with the methods described below for the analysis of specific RNAs and proteins.

**Cell components** The detailed analysis of cellular components may provide a deeper understanding of the behavior of cells in bioprocesses. Today, a number of methods can be applied to separate thousands of cellular compounds and even to quantify them. A few of the current methods, which were developed to handle the large complexity of biological samples, are briefly described below.

Generally, for all these methods the sampling and inactivation (quenching) of the cellular activities is a critical step taking into account the time frame of the chemical and enzymatic reactions as well as the synthesis and degradation processes. Each target compound or group of compounds needs an own protocol for sampling, inactivation, and stabilization, which has to be optimized for the organism and process of interest. **Table 3** summarizes a number of principles that have been described for the analysis of different target components. Generally, the time span from taking the sample out of the fermenter broth to complete quenching of the sample should be very short. Running bioreactors with a slight overpressure simplifies sampling. Additional underpressure in the sampling vial supports fast sampling. It is important to keep the sampling connection very small in comparison to the sample volume and/or to guarantee washing of the connection to avoid falsification of the analytical results by co-sampling of old material from the sampling pipe. The multiple sampling in very short intervals (milliseconds to seconds), has been a special challenge for which special devices have been constructed. The same problem of the inactivation interval also has to be considered in FIA. Therefore, different principles have been applied, such as concentric double lumen catheters, filtration modules (e.g., cross flow, hollow fibers), and ultrasonic waves in the megahertz range.

Quenching of the samples is necessary to freeze the target components at a state that does not deviate from their levels in the reactor. Generally, collection at a very low temperature is most favorable to inhibit enzymatic and chemical reactions, but freezing should be avoided if cells and media are separated in a later step, as thawing always leads to some cell lysis and release of cellular components into the medium. Quenching can be efficiently supported by chemicals such as sodium azide, formaldehyde, and methanol. Also, special cell inhibitors, such as

antibiotics, may be helpful, e.g., chloramphenicol for inhibition of protein synthesis, or protease and RNase inhibitors.

As in most cases at-time analysis is not practicable, the analysis protocol should contain an option for sample storage. Most common is the storage of aliquot samples at  $-70^{\circ}\text{C}$  or on liquid nitrogen.

Fast sampling has especially been of interest for metabolic flux analysis. This method is based on the analysis of a large number of cellular compounds. Mostly this method includes radioactive labeling, following fast sampling and analysis of the medium and cell fractions by nuclear magnetic resonance (NMR).

The offline analysis of selected metabolites of the cells during a bioprocess can be performed by MS, NMR spectroscopy, or chromatographic separation procedures. The NMR technique is based on the specific response of atomic nuclei that are exposed to a magnetic field. This technique is able to resolve the structures of small biomolecules and thus to determine selected metabolites during a bioprocess or for metabolic flux analyses. Advanced MS techniques allow a high throughput analysis of complex mixtures of metabolites by the determination of the specific masses of the metabolites.

Nucleotides are key metabolites playing a major role in energy metabolism as electron acceptors (NAD, NADP), in enzyme regulation (ATP, ADP, GTP), and in cell signaling (cAMP, ppGpp). Changes of their level and phosphorylation status belong to the earliest metabolic reaction of a cell to environmental signals. Therefore, their analysis has been interesting and challenging due to their high turnover rates. For fast quenching and extraction different procedures have been applied, such as direct sampling in formaldehyde, ice-cold perchloric acid, trichloroacetic acid, or concentrated KOH followed by neutralization. The selected method depends on the cell wall characteristics of the organism, the medium components, and may include additives such as ethylenediaminetetraacetic acid to complex divalent metal ions, which are activators of adenine nucleotide-converting enzymes. Different methods exist for the quantitative analysis including the detection of radiolabeled nucleotides, which is most sensitive, as well as luminometry and a variety of HPLC procedures. HPLC analysis is most suited for bioreactor analyses. Different HPLC techniques have been developed including ion exchange, reversed phase (RP), and ion-pair RP principles. Luminometric analysis is restricted to adenosine nucleotides. Radiolabeling of bioreactor samples is mostly not possible, although this is a highly sensitive method.

As mentioned above, chromosomal DNA and plasmid content of cells during a bioprocess can be monitored by flow cytometry. These cellular genomic constituents contain a decisive part of the blueprint of the bioprocess. For example, plasmids can carry recombinant genes, which code for the product formation of the cells. The stable distribution of these plasmids to the daughter cells is crucial for the yield of a bioprocess. Therefore, the analysis of the plasmid content of single cells is an important approach to monitor the productivity of the cells during recombinant bioprocesses. Another approach for the quantification of the plasmid number or DNA concentration is based on the real-time polymerase chain reaction (real-time PCR). Specific probes for selected sequences of the genes of interest, which are labeled with different fluorescence dyes, are used to quantify the plasmid molecules in a distinct number of cells throughout the PCR amplification. The quantitative detection of the DNA hybrids is realized by the detection of the bounded labeled specific hybridization probes or by double-strand DNA-specific fluorescence dyes like SYBR Green I.

The mRNA level of a bioprocess-relevant gene can be used as an early measure of its expression status. A simple but labor-intensive offline technique for the mRNA analysis of one or a limited number of genes is Northern blotting. Following the separation of the RNA sample in a polyacrylamide gel, the RNA is blotted on a membrane and detected by the hybridization of labeled sequence-specific probes. This technique does not only allow a quantitative analysis of the mRNA level but also gives information about the length and potential degradation products of the RNA.

Based on the knowledge of the base composition of a distinct bacterial genome, a global expression profiling of all genes of an organism can be performed by means of genomic DNA chips. The mRNAs are rewritten into cDNAs and labeled, usually with the fluorescence dyes Cy3 or Cy5. The labeled cDNA sample is incubated on the chip and binds at the chip surface by forming a duplex with its complement probe. The intensity of the hybridization signal allows an estimation of the level of distinct mRNAs in the investigated cell sample. The detection of the fluorescently labeled hybrids on the chip is usually based on confocal laser scanning.

The expression analysis by means of optical DNA chips is only useful for an offline analysis of selected critical bioprocess-relevant genes. The analysis time for the mRNA by these approaches from early cell disruption and RNA isolation to final data analysis lasts several hours. Alternative shorter and less labor-intensive techniques have been suggested and are

being developed. In comparison to common optical DNA chips, these techniques do not allow a parallel analysis of thousands of RNA species at one time, but are useful for process state analysis based on tens of key RNAs. One such approach is the real-time reverse transcription-polymerase chain reaction (real-time RT-PCR). This technique is also based on a rewriting of the mRNA with specific primers by reverse transcription into cDNA, which is then used as a template in the fast PCR reaction. Real-time RT-PCR allows the simultaneous analysis of ~10–40 mRNA species in ~1 h. The detection can be realized either by labeled specific hybridization probes or double-strand-specific fluorescence dyes.

Even faster analysis of mRNAs is possible with a sandwich hybridization system for which two oligonucleotide probes, acting either as capture or detection probe, are directly bound to the target RNA species. Although this method currently does not reach the sensitivity of real-time RT-PCR it has the advantage of being applicable for measurements directly in crude cell extracts. This method can be automated for large sample numbers in pipetting robots and has been combined with different read-out principles. An interesting recent development for bioprocess state analyses is an electrical chip-based read-out system for DNA/RNA hybrids by an electrochemical detection with interdigitated electrodes. This electrical chip technique is based on the coupling of the hybridization event to an enzymatic reaction, which produces a redox-active product. In this approach the mRNAs are efficiently captured by oligonucleotide probes located on magnetic beads or directly on the electrode surface. DNA/RNA hybrids are then detected with alkaline phosphatase-coupled DNA detection probes. The enzyme converts the redox-inactive substrate *para*-aminophenol phosphate into redox-active *para*-aminophenol, which by recycling between the electrodes acts as a second-stage signal amplifier.

The two-dimensional polyacrylamide gel electrophoresis technique (2D-PAGE) is used for the investigation of the protein pattern of a cell population, the proteome, at a distinct time point of a bioprocess. The proteome represents the sum of all proteins of one cell or cellular compartment based on the genome sequencing. The 2D-PAGE technique in combination with N-terminal protein sequencing or mass spectroscopic techniques, particularly matrix assisted laser desorption/ionization–time-of-flight MS, allows the identification of critical proteins that are relevant for the performance of biotechnological processes. Furthermore, the proteome analysis technique is used to characterize protein turnover or post-translational modifications, which are

important parameters for the quality control of recombinant protein production processes. The proteomics approach, however, has some limitations. Although 2D-PAGE analysis allows the identification of the majority of the proteins, it does not give a comprehensive overview of the gene expression activity of the cells. Critical proteins like hydrophobic, very small, or low abundant proteins cannot easily be visualized by the 2D-PAGE technique.

Selected proteins, which are of special interest for the monitoring of a bioprocess, can also be analyzed by protein chips. Protein chips are either based on antibodies, which capture the appropriate antigens out of a protein sample, or on different chromatographic surface properties, which attract only distinct proteins. The detection of antibody-based protein chips is done with labeled antibodies recognizing an additional suitable epitope of the target protein. These protein chips can be read out in a DNA chip laser scanner. The chromatographic protein chips possess, for example, different hydrophobic, hydrophilic, cation exchange, anion exchange, or immobilized-metal affinity surfaces. The proteins interacting with the chemistry of the chip surface can be analyzed in special protein-chip readers by a time-of-flight mass spectrometer.

The drawbacks of the proteomic approach can be partially circumvented by the DNA array technology. The combination of both techniques allows a comprehensive direct view on the physiological state of the cells during a bioprocess. The sequencing of the genomes in concert with proteome and transcriptome analyses, including the coverage of the most essential metabolites (metabolome approach) of different industrially relevant hosts, opens up completely new possibilities for solving problems connected with the control and optimization of biotechnological processes.

Metabolic changes in bioprocesses such as certain stress events are better reflected by the change of the synthesis rates of proteins than by the total composition of the cell. Therefore, in microbial physiology short-time labeling by radioactive precursors and following chasing by addition of the unlabeled form of the same precursor is a well-established principle. However, this method is difficult to apply in bioprocesses, where fermentation volumes are in the range of liters to m<sup>3</sup>. Such processes cannot easily be scaled down to the milliliter scale, which is commonly applied for these investigations. For offline labeling it must be taken into account that the conditions (especially aeration, nutrient supply, mixing) in the sampling vial are different from the fermenter and therefore very short labeling intervals (1 min) and reliable controls must be applied. Nevertheless,

the detection of synthesis rates has been applied for cell samples from fermentations. These analyses provide valuable information concerning the total cellular synthesis rates (e.g., for translation, transcription, and replication) of the production cells during a bioprocess.

## Introduction

Proteins are linear polymers of amino acids joined by peptide bonds. Proteins with  $M_r$  above 5000 Da are arbitrarily called polypeptides and those with smaller  $M_r$  are called peptides. They perform many roles: they carry oxygen in blood; they are part of the

muscles that lever bones; they reinforce teeth and bone; they are the antibodies that fight infection; they are some of the hormones that provide signals to organs; they regulate gene function; and some of the proteins are the enzymes that control metabolism.

Protein function is related to protein structure, which is considered on four levels: the primary structure, which is the specific sequence of amino acids joined together by covalent peptide bonds; the secondary structure, which is based on how amino acids interact, promoting protein folding; the tertiary structure, which represents the overall three-dimensional shape of the protein; and the quaternary structure, where single proteins, or subunits, combine to make up a multisubunit protein.

## Primary Protein Structure

There are 20 common amino acids that in various numbers and combinations form all proteins, although there are a few exceptions. The essential ingredient of an amino acid is the three-atom group nitrogen-carbon-carbon. The nitrogen is present as part of an amine group and, under certain physiological conditions is positively charged. The central carbon, or the  $\alpha$ -carbon, has a side group or residue that contributes much of the chemical and physical properties to each of the 20 amino acids. The last carbon is part of a carboxylate group and under certain physiological conditions is either neutrally or negatively charged. Individual amino acids are joined together enzymatically by the elimination of water in a condensation reaction that yields a covalent peptide bond between the carboxyl carbon of one amino acid and the amine nitrogen of another. **Figure 1** shows peptide bond formation.

The first amide atom is represented as  $N_i$ , where  $i$  is the number of the amino acid in the chain,

**Figure 1** Covalent peptide bond formation by condensation.

numbered from the amino end of the chain. The carbon to which the first carbon of the amino acid residue bonds is termed the  $\alpha$ -carbon,  $C_i^\alpha$ , and the carbon involved in the peptide bond is  $C_i'$ . The subsequent carbons in the side chain from the  $C_i^\alpha$  are termed  $C_i^\beta$ ,  $C_i^\gamma$ ,  $C_i^\delta$ ,  $C_i^\epsilon$ , and so on. The repeated atoms of  $N_i$ ,  $C_i^\alpha$ , and  $C_i'$  make up the backbone of the peptide. Three-dimensional crystal structures solved for small peptides have revealed the dimensions of the peptide group.

The average dimensions solved in many crystal structures show that almost all peptide bonds are in a *trans* configuration creating staggered residues due to steric hindrance between nonbonded atoms. One main exception occurs with the amino acid proline. Its cyclic side chain reduces the repulsion between atoms and so favors the *trans* and *cis* conformations equally (see **Figure 2**).

The expected length of a single C–N bond is 1.45 Å, as in the  $C^\alpha$ –N bond, and that of a C=N double bond is 1.25 Å. The actual length of the  $C'$ –N peptide bond is 1.33 Å, showing that it has partial double bond characteristics (40% double bond). Rotation can occur, in principle, around all three bonds  $\psi$ ,  $\phi$ , and  $\varpi$ , where  $\psi = \phi = \varpi = 180^\circ$ . This means that for a protein of 100 residues there are  $2 \times 10^{90}$  possible conformations, far more possible conformations than there would be protein molecules, even in a large sample. However, we know that a folded protein has a relatively stable conformation. This is due to many factors, one being the partial double bond characteristics of the  $C'$ –N peptide bond that limits it to a *trans* conformation (with the exception of proline), the atoms of the side chains restrict bond rotation due to excluded volume effects that dictate

**Figure 2** Diagram showing the typical *trans* conformation of the backbone atoms. Phi ( $\phi$ ) and psi ( $\psi$ ) bond angles determine the conformation. Dotted lines delimit a single amino acid.

that two atoms cannot exist in the same space as defined by the van der Waals radius and by repulsion effects of atoms in the side chains. The whole conformation is also stabilized by weak electrostatic interactions between atoms, and between atoms and the solvent and salts.

The chemical properties of amino acids make them weak buffers, so they can either accept or donate protons (see Figure 3). This means that their electrical properties can change with changes in pH. First, the amino and carboxyl groups of amino acids are ionizable. At a low pH, the amino and carboxyl groups will be protonated. The amino group will carry a positive charge and the carboxyl group will be neutral. The overall charge is therefore positive. At a high pH, both groups will be deprotonated and the overall charge will be negative. The pH at which the amino group is protonated and carboxyl group is deprotonated, and therefore has no overall charge, is said to be the amino acids' isoelectric point ( $pI$ ) (Table 1). This property of amino acids means that proteins are susceptible to changes in pH and salt concentration and that stability is dependent on interactions between protein, solvent, and intermolecular interactions. At a pH close to a protein's  $pI$ , these interactions cannot take place, which results in precipitation.

The properties of individual amino acids in the primary structure greatly affect the structure of a protein at the secondary, tertiary, and quaternary levels. In fact, a single mutation in the genetic code may alter only a single amino acid in a large protein but result in dramatic changes in structure. An example of this is the case of sickle-cell anemia, where a single amino acid change causes reduced function of hemoglobin. Hemoglobin comprises four subunits,  $2\alpha 2\beta$ . A single mutation in the gene that codes for the  $\beta$ -subunit of hemoglobin results in residue 6, Val, being replaced by Glu. Consequently, a charged

residue of a surface  $\alpha$ -helix is replaced with a hydrophobic residue. The hydrophobic region on the surface of the protein fits and binds into a hydrophobic pocket of a second hemoglobin molecule when in the deoxygenated form. The result is the polymerization of hemoglobin molecules in red blood cells. This causes the cells to deform into a sickle shape and their oxygen-carrying properties are lost. If the mutation only occurs in one gene copy, the effects are limited, but for homozygotes the disease is fatal without treatment.

The ability of proline to adopt a *cis* conformation in its peptide bond, for example, can create hairpin turns along the length of the protein. The thio groups of a cysteine side chain can be oxidized to form a covalent disulfide bridge between two adjacent cysteines. Disulfide bridges stabilize protein structure and can form large loops in proteins.

## Primary Structure Determination

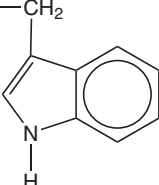

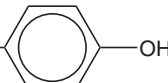

The amino acid sequence can be determined in a number of ways. The sequence can be established directly by combining a number of different techniques. The sequence of the protein can also be determined from the sequence of the gene that codes for it, and the primary, secondary, tertiary, and quaternary structures can be determined crystallographically, which gives a complete model of the protein.

The amino and carboxyl residues can be elucidated chemically by labeling them. Two common methods modify the N-terminal residue by the chemical addition of fluoro-2,4-dinitrobenzene or dansyl chloride. The protein is then hydrolyzed to its component amino acids. The amino acid labeled with fluoro-2,4-dinitrobenzene is colored yellow and that with dansyl chloride is fluorescent. This enables visualization of the labeled amino acid. Comparison of further

**Figure 3** Diagram showing the ionization of a single amino acid. Top species shows an amino acid's overall neutral charge when  $\text{pH} = pI$ . Bottom left shows protonation when  $\text{pH} < pI$ . Bottom right shows deprotonation when  $\text{pH} > pI$ .

chromatographic analysis of the labeled amino acids with standards identifies it. The Edman degradation is often used to determine the amino acid sequence. This involves the sequential degradation of the N-terminal amino acid. The protein is reacted with phenylisothiocyanate (PITC) to give phenylthiocarbamyl (PTC) derivative that makes the first N-terminal peptide bond unstable; mild hydrolyzation then liberates the first amino acid in the sequence but leaves the stable peptide bonds in place. The liberated amino acid can then be identified. The process is repeated and each amino acid in the chain is determined one at a time. This method has been automated to speed up the process and to make it more reliable, but it is not without its drawbacks.

The carboxyl group of the C-terminal amino acid is identified in a similar way, although the results are less reliable. One of the most common methods used involves converting all the C $_{\alpha}$  atoms into hydrazides. This liberates most, but not all, of the C-terminal residues in the sample and allows their identification. Further limitations occur as Asn and Gln cannot be liberated since their side chain amides are converted to hydrazides and Arg residues are converted to ornithine and are not liberated either. Another method uses acetic anhydride to form an oxalone specifically on the C-terminal residue. The converted residue can be labeled with deuterium or tritium and then liberated by hydrolysis and identified.

Mass spectroscopy is increasingly being used to resolve amino acid sequences due to recent developments in this technique. There are several different methods that can be used, but basically this method determines the mass-to-charge ratio of individual amino acids of a fragmented protein. The pattern of fragmentation can be extremely complex, but peptide bonds are mostly broken to cause the fragmentation. The patterns of fragmentation are known, and this allows the sequence to be determined.

The most commonly used, and most reliable, method for determining primary structure is the determination of the DNA sequence of the gene that codes the protein. It is necessary to know the sequence of the first and last 6–10 amino acids of the protein to be identified so that primers can be generated that correspond to the non-sense strand of the gene in question. Polymerase chain reaction (PCR) can then be used to ‘pull out’ a copy of the gene that can then be cloned, propagated, and sequenced. This method still has its challenges due to the redundancies of the DNA triplet code, where more than one triplet codes the same amino acid. If the wrong triplet is chosen in the primer then it may not hybridize to the corresponding sequence in the gene. Proteins also often undergo posttranslational

modification and only knowing the gene sequence will not give any information as to what these might be.

## Secondary Protein Structure

$\alpha$ -Helices,  $\beta$ -sheets, and triple helices are three types of secondary structures. All are formed and stabilized by noncovalent interactions, mainly hydrogen bonds. Proteins can contain only one or mixtures of secondary structure as well as portions of the protein that contain structures difficult to describe but not less ordered, such as reverse turns and  $\beta$ -bends.

$\alpha$ -Helices are regular right-hand turns of amino acids 3.6 residues long; 5.41 Å. Hydrogen bonding between the first backbone carbonyl oxygen atom and the fourth residue NH group stabilizes the structure; van der Waals interactions across the axis further stabilize the structure. There are some rare exceptions to this general scheme where hydrogen bonding can occur between three residues ( $3_{10}$ -helix) or between five residues ( $\pi$ -helix). These structures are much less stable than general  $\alpha$ -helices and are not normally favored. Any of the 20 amino acids can participate in an  $\alpha$ -helix but some are more favored than others. Ala, Glu, Leu, and Met are most often found in helices whereas, Gly, Tyr, Ser, and Pro are less likely to be seen. Proline, for instance, is rarely seen as its backbone nitrogen is bonded to its cyclic side group and cannot participate in hydrogen bonding. When prolines are found in  $\alpha$ -helices, they tend to cause the helix to bend due to steric hindrance caused by its side group. They can be found as the first or last residue in the helix where they do not cause bending. The side groups of the other amino acids point out and down relative to the helix. In globular proteins, those that are hydrophobic tend to be on one side of the helix and interact with other amino acids of the protein, and those on the other side are generally hydrophilic and interact with the solvent. For this reason,  $\alpha$ -helices of globular proteins are predominantly found on the protein surface and have polar, hydrophobic, and hydrophilic amino acids. On average,  $\alpha$ -helices in globular proteins have 11 residues,  $\sim 17$  Å long. Some  $\alpha$ -helices have mainly hydrophobic residues, which are found buried in the hydrophobic core of a globular protein, or are transmembrane proteins.

$\beta$ -Sheets are formed by the interactions between parallel regions of a protein chain. These either run in the same direction, parallel; or in the opposite direction, antiparallel. These structures are stabilized by hydrogen bonds between backbone carbonyl oxygen atom and the hydrogen of the amino group. In parallel  $\beta$ -sheets, the distances between the carbon

and nitrogen involved in binding on one strand and on the other differ. This means that the hydrogen bonds are at an angle in relation to the protein strand. This is thought to make parallel  $\beta$ -sheets less stable than antiparallel  $\beta$ -sheets. In antiparallel  $\beta$ -sheets, the atoms on opposite strands involved in hydrogen binding are the same distance so that hydrogen bonds are at  $90^\circ$  to the strand.  $\beta$ -Sheets are not flat but have a pleated appearance due to the  $C_i^\alpha$  atoms being successively above and below the plane of the sheet. The side groups are also successively above and below the plane of the sheet and they, therefore, cannot interact with each other. They do have significant interactions with neighboring side chains and with their backbone. Proteins can contain parallel  $\beta$ -sheets, antiparallel  $\beta$ -sheets, or a mixture of both, although mixed proteins account for only 20% of proteins with  $\beta$ -sheets. The strands are typically 5–10 amino acids long and  $\beta$ -sheets contain 2–15 strands. The strands in  $\beta$ -sheets always have a right-handed twist.

$\alpha$ -Helices and  $\beta$ -sheets make up  $\sim 50\%$  of a protein's secondary structure. These structures are connected by looped regions that change the direction of the protein strand.  $\beta$ -Bends connect subsequent strands in a  $\beta$ -sheet, so that they are aligned parallel. Each bend consists of two amino acids, usually Pro because of the flexibility of its C'-N peptide bond and Gly because its side chain gives the least crowding in the tight turn. The structure is stabilized by hydrogen bonding between the residues immediately before and after the bend.  $\Omega$ -loops are so called as they have the general shape of the letter omega. These are usually 6–16 residues long and connect  $\alpha$ -helices and  $\beta$ -sheets. They are predominantly found at the protein surface in globular proteins or connecting membrane  $\alpha$ -helices at the cytoplasmic or extracellular face. These structures are often involved in recognition processes. Some of the remaining structure is disordered but nonetheless important, as these regions often confer great flexibility to proteins essential to their function.

## Secondary Structure Determination

Secondary structure is difficult to determine directly, although models of a protein can be built using data gathered with nuclear magnetic resonance (NMR) or by X-ray diffraction of protein crystals. Because of these difficulties, unknown secondary structure is often predicted based on what is known about secondary structure of other proteins.

Many methods have been developed to try to predict secondary structure, based on the knowledge of the primary structure of a protein. Knowledge of the

position and properties of amino acid allows assignment of probable structure, although this can be unreliable and very limited. It is most successful in predicting the  $\alpha$ -helices involved in transmembrane stretches, and there are a number of computer programs that can do this because of the hydrophobic nature of the  $\alpha$ -helices. These programs also try to predict  $\alpha$ -helices and  $\beta$ -sheets of globular proteins but are much less reliable because they use information from models of known structure based on sequence similarities. Certain secondary structures, folds, or motifs, are conserved in families of proteins. Prediction programs and sequence comparisons can often spot these, but it is very difficult to predict how individual amino acids in the structure are influenced by their local environment, so these predictions often do not give an absolute determination of secondary structure.

Circular dichroism (CD) spectroscopy can reliably assign the proportions of  $\alpha$ -helices and  $\beta$ -sheets in a protein based on the differing spectral properties of their backbones. This does not give any more information about secondary structure but is useful because it does tell that a protein is folded, although not whether it is folded correctly. Comparison of CD spectra for a protein of unknown structure with that of known structure can provide a good interpretation.

## Tertiary Protein Structure

Tertiary structure is the folding of the secondary structure into distinct arrangements known as domains. This occurs spontaneously in cells in one to several seconds and is driven by the properties of the amino acid side chains. Hydrophobic side chains cannot break the hydrogen bonding of solvent water molecules and so the nonpolar residues Val, Leu, Ile, Met, and Phe tend to bury themselves in the center of the protein; this is one of the main forces that drives protein folding. The core of a globular protein is tightly packed, thus excluding most water molecules, and is highly ordered. Hydrophilic side chains favor the surface of globular proteins. Charged polar residues Arg, His, Lys, Asp, and Glu are mostly found on the surface and the uncharged polar residues Ser, Thr, Asn, Gln, Tyr, and Trp are found on both the interior and on the surface and are the hydrogen bond donors that help stabilize the tertiary structure. Ionic forces also contribute to structure stabilization at physiological pH. Asp, for instance, carries a negative charge and Glu carries a positive charge. These charges attract each other when in close proximity and form a salt bridge.

A protein can have one or several distinct domains linked by loop regions. These domains contain

100–200 residues typically and can give functional as well as structural properties to the protein. Protein domains can be divided into three main groups;  $\alpha$ -domains,  $\beta$ -domains, and  $\alpha/\beta$ -domains.  $\alpha$ -Domains consist mainly of  $\alpha$ -helices at the protein's core,  $\beta$ -domains consist of antiparallel  $\beta$ -sheets, and  $\alpha/\beta$ -domains consist of  $\beta$ -sheets surrounded by  $\alpha$ -helices in a  $\beta\alpha\beta$  conformation.

$\alpha/\beta$ -Domains are the most frequent structures in globular proteins. They can be divided into three main classes, depending on their conformation. The first is the  $\beta$ -barrel, characterized by a barrel-like structure where  $\alpha$ -helices connect parallel  $\beta$ -strands on the outside of the barrel. The second is the Rossman fold, after Michael Rossman, who first described the structure, which is an open, twisted

$\beta$ -sheet not unlike the rungs of a ladder surrounded on both sides by  $\alpha$ -helices. These folds are often associated with nucleotide binding (see Figure 4, the ATP binding domain of hexokinase for an example). The third is called the horseshoe fold as its shape resembles a horseshoe. The  $\beta$ -strands form a curved structure with  $\alpha$ -helices on the outside face of the curve. The horseshoe fold is also often called leucine-rich motif as it contains repetitive leucine residues.

$\beta$ -Barrels often have active sites in very similar positions, usually at the carboxy end of the barrel. This is also true for the open folds but binding of ligands is very different. The open folds do not form a cylinder as in the barrel structures. Instead, binding occurs in a cleft formed by loops linking and going in and out of the sheet. The domain structures are very

**Figure 4** Cartoon and topology diagram of the ATP binding domain of hexokinase. The crevice formed between  $\beta$ -sheets 1 and 4 is the site of ATP binding.

similar even though their amino acid sequences may differ somewhat. It is this similarity in structure and function that is used to assign proteins into families.

$\beta$ -Domains are the second most frequent structure in proteins and are the most diverse. They generally consist of two antiparallel sheets packed together to form a barrel and can be divided into three domain groups. Up-and-down  $\beta$ -barrels are adjacent antiparallel strands connected by hairpin loops. These structures are found in many proteins, which include transport proteins and viral coat proteins as well as many others. Greek key motifs are barrel structures with a basic unit made up of four-stranded antiparallel  $\beta$ -sheets. The first strand is connected to the fourth strand by a hairpin loop. Strands 2 and 3 are connected by a loop on the opposite end of the barrel (see Figure 5). These motifs are repeated to form the barrel. The Greek key motif is a component structure of the jelly-roll domain. A simple illustration is given in Figure 6.

**Figure 5** Topology diagram showing the organization of an antiparallel  $\beta$ -sheet into a Greek key motif.

**Figure 6** Topology diagram showing the organization of two Greek key motifs into a jelly-roll fold.

## Tertiary Structure Determination

It is possible to predict the tertiary structure of a protein by comparing the amino acid sequence of the unknown protein with those whose structure is known. Structures can be assigned based on unique folds or domains that have conserved amino acids and, although the amino acid sequence of a specific fold may differ, amino acids with similar properties are conserved to maintain the structural and functional properties of the protein. It is possible, with relative accuracy, to assign proteins to a particular protein family in this way.

The complete protein structure can be derived by X-ray crystallography. The technique requires the target protein to be purified to homogeneity and concentrated, typically to  $5\text{--}10\text{ mg ml}^{-1}$ . The buffer that supports the protein is then slowly exchanged into a supersaturated solution containing a precipitant at a given pH. Salts and polyethylene glycol are commonly used precipitants. The type and concentration of precipitant and pH used are generally arbitrary as it is extremely difficult to predict under which conditions the protein will precipitate to form crystals. Crystal screens of  $\sim 100$  conditions are typical as a first step to derive satisfactory conditions for precipitation.

**Figure 7** X-ray crystallographically derived 3D model of snail acetylcholine binding protein.

A crystal is a regular repeating array of many protein molecules. The level of order in the crystal determines how well it will diffract X-rays when placed in an X-ray beam. A protein crystal scatters X-rays when placed in the beam emitting its own source of X-rays. The direction and intensity of these emissions are recorded on X-ray detection plate. The pattern of diffraction can provide information about the individual atoms of the crystal, but extracting this information requires significant computation. The result is an electron density map that can be used to interpret the structure of the target protein, although this in itself is complicated (see **Figure 7** for an X-ray crystal model of acetylcholine binding protein).

### Quaternary Protein Structure

Protein subunits, or the tertiary structures, can come together to produce a multisubunit protein. These can be two to several identical or different subunits. They may be functionally distinct or can act together cooperatively. Hydrogen and ionic bonds hold them together as well as disulfide bridges in some cases. Subunits may remain together for function or come together as part of their function.

### Quaternary Structure Determination

The quaternary structure is usually determined by X-ray crystallography, as described previously. However, when crystallographic data were difficult or impossible to gather, electron microscopy had provided some clues to quaternary structure.

It is relatively simple to determine the multisubunit composition of a protein experimentally. By disrupting the interactions that hold multisubunits together, it is possible to establish the molecular weight of each by using size-exclusion chromatography. If the method is repeated without bond disruption, the composition can be determined by using simple mathematics. Ultracentrifugation of a protein sample in a viscous glucose solution can ascertain molecular weights based on their sedimentation coefficients, and, in conjunction with light scattering, which measures the molecular dimensions of proteins in solution, some information about how the multisubunit protein is organized can be determined.

The need for automated methods to determine the primary structure of a protein was never more apparent than in Sanger's labor-intensive landmark and classic effort of the amino acid sequence determination of insulin in the early 1950s. Practically coincident in time with this successful *tour de force* was the development of a straightforward chemical method for the determination of the amino acid sequence of a peptide or protein by Edman, who not only fulfilled this need but provided the groundwork for automation of the method. Seventeen years later, Edman developed the first automated spinning-cup, or liquid-phase, sequencer. This technology became virtually universal and routine for the determination of the primary structure of any peptide, protein, or glycoprotein. Edman chemistry, also known as the phenylisothiocyanate degradation, remains in the

1990s as the most generally accepted procedure for the efficient sequencing of both small peptides and large proteins, although many variations on the basic theme have been developed to optimize the system.

Currently, Edman chemistry manifests itself in three modes: the automated liquid phase, solid phase, and gas phase, all three of which developed from the manual method, which today still has some appeal and usefulness in some laboratories. The most significant development in phenylisothiocyanate chemistry was the advent, due to Edman and Begg, of the automated spinning cup in 1967, which was successfully developed by Beckman Instruments. Just four years later, the first automated solid-phase sequencer, from Laursen, was described and developed by Sequemat, a Boston-based company founded by two graduate students of Laursen. Both of these machines overcame most of the limitations (lack of speed and labor-intensiveness) of the manual method, although both technologies had inherent problems of their own. For example, the spinning-cup sequencer encountered large peptide extractive losses when handling small peptides, and the solid-phase method

A crystal is a regular repeating array of many protein molecules. The level of order in the crystal determines how well it will diffract X-rays when placed in an X-ray beam. A protein crystal scatters X-rays when placed in the beam emitting its own source of X-rays. The direction and intensity of these emissions are recorded on X-ray detection plate. The pattern of diffraction can provide information about the individual atoms of the crystal, but extracting this information requires significant computation. The result is an electron density map that can be used to interpret the structure of the target protein, although this in itself is complicated (see **Figure 7** for an X-ray crystal model of acetylcholine binding protein).

### Quaternary Protein Structure

Protein subunits, or the tertiary structures, can come together to produce a multisubunit protein. These can be two to several identical or different subunits. They may be functionally distinct or can act together cooperatively. Hydrogen and ionic bonds hold them together as well as disulfide bridges in some cases. Subunits may remain together for function or come together as part of their function.

### Quaternary Structure Determination

The quaternary structure is usually determined by X-ray crystallography, as described previously. However, when crystallographic data were difficult or impossible to gather, electron microscopy had provided some clues to quaternary structure.

It is relatively simple to determine the multisubunit composition of a protein experimentally. By disrupting the interactions that hold multisubunits together, it is possible to establish the molecular weight of each by using size-exclusion chromatography. If the method is repeated without bond disruption, the composition can be determined by using simple mathematics. Ultracentrifugation of a protein sample in a viscous glucose solution can ascertain molecular weights based on their sedimentation coefficients, and, in conjunction with light scattering, which measures the molecular dimensions of proteins in solution, some information about how the multisubunit protein is organized can be determined.

The need for automated methods to determine the primary structure of a protein was never more apparent than in Sanger's labor-intensive landmark and classic effort of the amino acid sequence determination of insulin in the early 1950s. Practically coincident in time with this successful *tour de force* was the development of a straightforward chemical method for the determination of the amino acid sequence of a peptide or protein by Edman, who not only fulfilled this need but provided the groundwork for automation of the method. Seventeen years later, Edman developed the first automated spinning-cup, or liquid-phase, sequencer. This technology became virtually universal and routine for the determination of the primary structure of any peptide, protein, or glycoprotein. Edman chemistry, also known as the phenylisothiocyanate degradation, remains in the

1990s as the most generally accepted procedure for the efficient sequencing of both small peptides and large proteins, although many variations on the basic theme have been developed to optimize the system.

Currently, Edman chemistry manifests itself in three modes: the automated liquid phase, solid phase, and gas phase, all three of which developed from the manual method, which today still has some appeal and usefulness in some laboratories. The most significant development in phenylisothiocyanate chemistry was the advent, due to Edman and Begg, of the automated spinning cup in 1967, which was successfully developed by Beckman Instruments. Just four years later, the first automated solid-phase sequencer, from Laursen, was described and developed by Sequemat, a Boston-based company founded by two graduate students of Laursen. Both of these machines overcame most of the limitations (lack of speed and labor-intensiveness) of the manual method, although both technologies had inherent problems of their own. For example, the spinning-cup sequencer encountered large peptide extractive losses when handling small peptides, and the solid-phase method

never achieved the sequencing efficiencies of the liquid-phase machine with large proteins. To a large degree, these deficiencies were overcome with the development of the gas-phase sequencer of Hunkapiller and Hood in 1981. Applied Biosystems Inc., founded by Hood, commercially developed the first gas-phase sequencer, which is virtually ubiquitous in modern protein sequencing laboratories throughout the world.

## Edman Chemistry and the Manual Method

Edman degradation is a three-step procedure consisting of the coupling of phenylisothiocyanate (PITC) to the  $\alpha$ -amino group of a peptide or protein, cleaving the amino-terminal amino acid (via cyclization in strong per-fluorinated acid, typically trifluoroacetic acid (TFA), to a 2-anilino-5-thiazolinone), and converting the resulting thiazolinone in aqueous acid to its more stable isomer, the phenylthiohydantion (PTH) amino acid.

Coupling takes place most rapidly and completely under alkaline conditions at a pH above the pK of the amino group (pH = 7.8), at which it is uncharged, and at pH below 10, above which PITC is hydrolyzed. The coupling medium is a mixture of aqueous and organic solvents to enhance the solubility of both the peptide and the PITC reagent.

In the manual mode, coupling of the peptide is performed under nitrogen in a stoppered 5-ml conical centrifuge tube for 30 min at 54°C in 100  $\mu$ l of 0.4 mol l<sup>-1</sup> dimethylallylamine (DMAA) buffer in propanol–water (60:40 v/v), previously adjusted to pH 9.5 with TFA. Following coupling, a single extraction with 0.1 ml of benzene is performed and the organic phase is discarded. Cleavage is accomplished with 75  $\mu$ l of TFA under nitrogen at 54°C for 5 min. Cleavage products are dried under a stream of nitrogen for 30 s. The TFA-treated thiazolinone amino acid is extracted with 0.15 ml of benzene and, following drying, is converted to its PTH isomer in 0.2 ml of 1 mol l<sup>-1</sup> HCl at 80°C for 10 min. The PTH amino acids are then identified most commonly by liquid chromatography (LC). Alternative manual methods are available and are described in great detail by Edman (1950), and reviewed by Niall (1973), Allen (1981), and Schlesinger (1988) (see Further Reading).

One useful advantage of the method is that four to six peptides can be analyzed simultaneously, each cycle of degradation taking ~1 h. This multiple sample sequencing technique is especially useful for screening the chromatographic elution profile of a

mixture of peptides with respect to their quantitative yields and N-terminal sequence.

## Automated Liquid-Phase Sequence Analysis

The advent of the liquid-phase sequencer marked the beginning of the era of data acquisition of protein sequences in the early 1970s. The machine fully automated each of the three steps of Edman chemistry. In the coupling stage, buffer and PITC are delivered to a rapidly rotating cup to which the protein sample has been applied. Following coupling, extraction of excess of PITC and nonvolatile buffer is accomplished by delivery of a flow of organic solvents, which are removed by a scoop at the top of the spinning cup. Remaining buffer and derivatized protein are then dried *in situ*. Cleavage is accomplished by the automated delivery of TFA, followed again by a drying step. Extraction of the cleaved thiazolinone is effected by delivery of excess organic solvent. In the older machines, conversion to the PTH amino acid was performed manually but in the more modern devices the thiazolinones are automatically converted. A complete description of the liquid-phase sequencer has been given by Edman and Begg (1967), Niall (1973), Waterfield and Bridgen (1975), and Edman (1975).

Since the mid-1970s a number of refinements have been introduced to improve the spinning-cup sequencer's performance and efficiency. These include a cold trap to provide a better vacuum system and an automated conversion device to improve the recovery of the PTH amino acids, such as those of serine and threonine. In addition, combined delivery of benzene and ethyl acetate has been introduced to decrease peptide and protein extractive losses while still effecting removal of Quadrol, a quarternary amine buffer, and excess PITC. To achieve the same efficiency in sequencing small peptides, volatile coupling buffer systems such as dimethylallylamine and dimethylbenzylamine have been instituted in this automated methodology. Other alternative approaches have been used in conjunction with these peptide systems to decrease extractive loss in solvent washes. One involves modification of the peptide itself by reacting the  $\alpha$ - and  $\epsilon$ -amino groups of the peptide with naphthyl or 4-sulfonaphthyl isothiocyanate to render the peptide more polar, and hence less soluble, in organic solvent washes. A second method involves film-stabilizing reagents such as Polybrene. This reagent, although used initially in the liquid-phase sequencer, is currently used routinely and successfully in the gas-phase sequencer described below.

## Automated Solid-Phase Sequencing

In an attempt to decrease peptide and protein extractive loss, covalent attachment of peptides to insoluble supports was developed by Laursen in 1966. Numerous solid-phase supports are available. These include the original amino-polystyrene and triethyltetramine-polystyrene and, more recently, 3-amino-propyl glass, diisothiocyanate glass, and iodoacetyl glass. These porous glass supports have proved generally to be more effective for coupling to proteins than the polystyrene resins. These reagents couple to the  $\alpha$ - and  $\epsilon$ -amino groups of the protein, so that major disadvantages are that peptide covalent attachment is lost when sequence analysis proceeds through the last lysine residue and that the amino-coupled residue remains unidentified. For these reasons, the ideal site of attachment is the carboxy-terminal residue. However, no generally satisfactory method is available, although carbonyl diimidazole, carbodi-imide, and trifluoroacetic anhydride have been used with success in some cases. Attachment of the  $\alpha$ -amino groups of lysine, the side-chains of cysteine, aspartic and glutamic acids, and methionine to insoluble supports has been successfully accomplished, although the coupling yields, regardless of the procedure, remain variable. Nevertheless, the solid-phase method provides a wide variety of sequencing strategies to complete structure determination of relatively large proteins.

## Automated Gas-Phase Sequencing

The gas-phase sequencer was the first instrument designed to handle microquantities (0.5 pmol) of both peptides and proteins and avoid the extractive loss problems of the spinning-cup sequencer as well as the covalent attachment problems of the solid-phase approach. The gas-phase apparatus combined the miniaturization and efficient chemical flow circuitries of the solid-phase column system with the ease of sample application of the spinning-cup sequencer. In the gas-phase approach the sample is embedded in a film of Polybrene on the surface of a glass microfiber filter disk within the reaction cartridge. Because the sample is not covalently attached to the support, coupling base and cleavage acid must be delivered as vapors (carried by a stream of argon), which diffuse into the Polybrene film to effect Edman chemistry. Solvent washing of the film to remove excess reagent is very efficient, so that small solvent and reagent volumes contribute to minimal contamination.

The newest version of the gas-phase sequencer is the so-called pulsed liquid sequencer. Microvalving technology, designed in the original machine, is used

to deliver precisely pulses of liquid reagent to wet the sample disk without flowing past it. Once reactions are complete, volatile reagents are removed by evaporation in a stream of argon gas passing through the reaction chamber. The use of pulses of liquid reagents rather than the continuous flow of reagent gases (TFA and triethylamine) significantly increases reaction rates and decreases cycle times.

The newest gas-phase sequencers also incorporate an automated conversion chamber to facilitate the on-line analysis of the PTH amino acids by micro-bore LC. All of these features facilitate rapidity and high sensitivity in microsequencing of peptides and proteins and have drastically decreased the amounts of material needed for structure determination to the extent that direct N-terminal sequence analysis of over 20 residues from a 2-D gel is possible. As a result, this methodology has altered the strategy for protein isolation from the tissue in which it was initially detected.

With the realization that direct sequencing from 1-D and 2-D gels was becoming feasible in the mid-1980s, attention was focused on optimization of direct transfer of protein samples from gels to the sequencer cartridge. This process became known as electroblotting. The two major classes of blotting media used for this application have been either glass-fiber filter (GF/C) or inert polymer-based membranes. Included in the class of glass fiber type media are derivatized GF/C (i.e. aminopropyl, quaternary ammonium, siliconized-glass fiber (SGF)) and non-covalently modified GFC coated with quaternary ammonium polybases (polybase GFC). The most commonly used nonglass, polymer-based membranes are prepared from poly(vinylidene difluoride) (PVDF). Initial success in this direction was achieved using PVDF membranes commercially referred to as Immobilon-P.

For this technique to be effective, however, numerous problems had to be either circumvented or overcome. These included variability in electrotransfer for different proteins, long times for adsorption of proteins from solution onto PVDF membranes, variable recovery due to protein selectivity, and staining and destaining methods that decrease sequencing yields. One successful method circumvents these problems through the use of centrifugation of dissolved samples through a PVDF membrane and subsequent washings to remove contaminants such as trisglycine. Another alternative is the implementation of a modified reaction cartridge within a gas-phase sequencer for direct sequencing on polymeric membranes. This redesigned reaction vessel implements a vertical (rather than horizontal) cross-flow type reactor to accommodate the PVDF membrane.

## Identification of the PTH Amino Acids

Sequence analysis of a peptide or protein occurs in two parts. The first is based on the chemistry of Edman degradation reviewed above. The second is the identification of the resulting PTH amino acids following that degradation. The most popular method for the identification of the PTH amino acids is LC, which was initially developed for the purification of intact peptides and proteins or their fragments. Although thin-layer and gas-liquid chromatography (GLC) have been used for the identification of the PTH amino acids, LC is the technique of choice for many reasons. LC can rapidly (20–30 min) resolve and quantify all 20 PTH-derivatized naturally occurring amino acids; it is easily automated and more sensitive than thin-layer chromatography or GLC; and it is not as labor-intensive, expensive, or equivocal as back-hydrolysis to free amino acids.

A typical LC system consists of hydrophobic liquid-bonded phase column packings (such as a cyanopropyl, phenyl alkyl, C<sub>8</sub>, or C<sub>18</sub>) as the stationary phase. The mobile phase consists of a buffered aqueous solution, such as 0.01 mol l<sup>-1</sup> sodium acetate, pH 5.5, and a miscible organic phase, such as acetonitrile, at a temperature of 40–62°C. The mobile phase is run either isocratically or with an increasing percentage of organic phase (gradient). Various parameters, such as temperature, organic solvent gradient, and pH of the aqueous buffer, can be manipulated so that separation of all 20 PTH amino acids as well as side-products of Edman degradation (diphenylthiourea (DPTU) and dimethylphenylthiourea (DMPTU)) are baseline-resolved in a single analysis. In addition, some PTH amino acids such as PTH histidine and PTH arginine are very sensitive to pH and salt concentration and their elution peaks can easily be placed in gaps between peaks of other PTH amino acids in the elution profile. The first description of reversed-phase gradient elution of the PTH amino acids was that of Zimmerman in 1977, but some two dozen other systems have been described. With modern LC instrumentation employing microbore gradient pumps, low noise, variable-wavelength UV absorbance detectors and specially formulated microbore columns, separation and detection of subpicomole quantities of PTH amino acids has become routine. In addition to these recent improvements, the use of radioactivity has also been used to increase sensitivity in the identification of the PTH amino acids. This involves the use of a radioactive flow detector in series with the UV detector. The PTH amino acids can be labeled using [<sup>14</sup>C]PITC or [<sup>15</sup>S]PITC during the sequencing of unlabeled peptides or proteins, or the protein can be

intrinsically labeled prior to sequencing. Using both labeled and unlabeled PTH norleucine as marker, superposition of the radioactive and UV profiles aligning the norleucine peaks identifies the radioactive PTH amino acid unknown.

## Optimization of Sequencing Data

Ideally, in sequencing one protein, one would expect a single PTH amino acid after each cycle of the Edman degradation. In the real world, this is never the case: each chromatogram contains variable amounts of the PTH amino acids for several reasons. (1) Protein or peptide samples are unlikely to be absolutely pure. (2) Repeated exposure of the protein sample to cleavage acid during sequencing can cause low-level acid-catalyzed cleavage of the peptide chain giving rise to other N-termini that can participate in Edman chemistry. Thus, as the degradation proceeds, the PTH amino acid background increases. (3) While this is occurring, the recovery of the expected PTHs is slowly decreased during sequencing by side-reactions that block the amino terminus or by physical extractive losses of sample from the reaction chamber. (4) Removal of an amino-terminal amino acid at any given cycle of Edman chemistry is incomplete, appearing, therefore, to some variable degree, at the next cycle of degradation. This carry-over, or lag, is cumulative, resulting eventually in the identification of the PTH amino acid being out of phase with the sequence analysis or expected order of release of amino acids during sequencing. (5) The relative recoveries of the PTH amino acids from Edman chemistry vary greatly. Some, such as leucine, are recovered almost quantitatively, while others, such as serine and threonine, are largely destroyed before analysis. (6) LC sampling volumes also contribute to ambiguity in the PTH assignments. These factors, summed together, make correct amino acid assignments ever more difficult as sequence analysis proceeds further into the polypeptide chain.

Because of the large number of variables that are virtually impossible to control manually, LC peak-integration systems have been employed to translate these analog signals into a simpler set of digital numbers. This process, initially introduced in 1971, has evolved into a system of fully computerized data analysis and data reduction systems. Here, the computer first collects and stores digitized LC detector output. Detector baseline drift and high-frequency noise from the chromatograms are removed by application of digital filters, and peaks corresponding to the PTHs are located, quantified, and stored for all cycles in a sequencer run file for each PTH amino acid. A recursive least-squares fit defines the background

levels of each individual PTH amino acid as a function of the cycle. Comparison of signal and background levels on the basis of their standard deviations then permits automated objective assignments of the amino acid sequence. This assignment can be further refined by additional routines that correct for sequence lag from incomplete Edman chemistry and for variability in PTH sampling by the LC system. This combination of baseline, background, and lag correction routines decreases the ambiguity in amino acid identification and allows amino acid sequence assignments with a defined level of statistical confidence. This computerized capability permits significant extension of assignable sequence length over previously unadjusted recoveries.

### **Novel Applications of Automated Protein Sequencing**

Unfortunately for the protein chemist, automated protein sequencing in most cases is no longer the method of choice for determining the primary structure of large proteins. This is because DNA sequencing is more rapid and less laborious in terms of obtaining peptide fragments, each of which has to be sequenced, with sequence overlaps, and because an amino acid sequence of a protein can be inferred from its corresponding gene.

Nevertheless, protein sequencing frequently plays a crucial role in the DNA sequencing process. For example, proteins purified by following the activity associated with them can be sequenced to obtain limited sequence information. These data then can be used to construct oligonucleotide probes to assist in the identification of the corresponding gene from a cloned library. Once identified and isolated, the gene can be amplified and sequenced.

This information, however, defines only the primary translation product. The post-translational processing events crucial to the biological activity of many proteins can only be determined by direct structural analysis of the protein itself, such as determining the site of proteolytic processing and side-chain modification, including glycosylation and phosphorylation. In a similar fashion, site-specific sequencing also defines amino acid side-chains labeled by active site or other chemical modifications.

In addition, the quantitative nature of Edman degradation lends itself to determining the purity of a given preparation and the homogeneity of material in chromatographic column effluents, as described above under manual methods. Quantitative sequencing can also be used to define the stoichiometry of multi-subunit proteins that perform many of the complex enzymatic and structural functions.

Another important application of protein sequencing is in the field of solid-phase peptide synthesis. With the rapid development, success, and popularity of solid-phase peptide synthesis, automated peptide and protein sequencing has found a number of important uses and applications in this burgeoning field. By the very nature of the fact that protein sequencing represents the reverse process of solid-phase peptide synthesis, sequencing offers a unique method for evaluating the products of solid-phase synthesis. Firstly, sequencing can be used to verify the order of amino acids following assembly on to the insoluble support prior to its cleavage from the resin on which it was synthesized. In so doing, sequencing can determine sites of difficulty in synthesizing a given peptide, i.e. sites of deletion of amino acid addition (or the presence of failure sequences). This sequencing application is referred to as 'preview analysis' because the sequence C-terminal to the deleted amino acid appears one residue amino terminal to its expected position in the sequence. Peptide resins from the solid-phase peptide synthesizer can easily and directly be applied to the gas-phase sequencer cartridge so that sequencing of peptide resins is routine in most core-facilities laboratories.

Another very important way in which protein sequencing can be used to characterize products of solid-phase peptide synthesis is in the detection of the presence and removal of amino acid side-chain-protecting groups in synthesis. This is because most side-chain-protecting groups used in *t*-butyloxycarbonyl (but not in 9-fluorenylmethoxycarbonyl) peptide synthesis are stable to reagents in protein sequencing and the PTH side-chain-protected amino acids resolve easily from their unprotected PTH amino acid counterparts. Thus, the sequencing of peptide resins establishes the integrity of side-chain-protecting groups prior to cleavage of the peptide from the resin and side-chain removal during HF treatment. Similarly, direct sequencing of the crude synthetic product following HF cleavage provides an accurate indication of the degree of removal of the side-chain-protecting groups as well as other effects of HF on the crude product. Carrying the solid-phase synthetic process further, sequencing can be used to evaluate the degree of homogeneity of the final synthetic product following chromatographic purification. Thus, it is clear that protein sequencing is an invaluable tool for monitoring virtually each stage of the solid-phase synthetic process.

Recently, sequencing has found a very novel application in epitope selection by screening universal peptide libraries in a process called *in vitro* selection. These libraries are generated by the solid-phase peptide synthesis of peptides prepared in random fashion

of any desired length, but in a very particular way. The quintessence of the method is that the random peptides are prepared in such a manner that only one random peptide resides on one particular bead on which the peptide is constructed. This feat is accomplished by performing 20 separate coupling reactions with each of the 20 naturally occurring amino acids, then mixing or randomizing the amino acid or peptide resin to which the next amino acid has been coupled, dividing the amino acid resins into, again, 20 portions and coupling the next amino acid to the growing peptide chain. In such a way, for example, after just two couplings there is a total of 400 randomly prepared peptides, each bead containing only one peptide, but obviously many beads containing the same peptide. However, after each additional coupling followed by randomization of the peptide resins, the number of beads containing the same peptide rapidly diminishes. In fact, after eight or so couplings, over 25 billion ( $20^8$ ) different peptides exist. Once these libraries have been constructed, they can be screened using a particular antibody to which a fluorescent tag has been covalently bound. The antibody binds and recognizes theoretically only one peptide epitope or amino acid sequence that fits its binding site. Then, simply using a microscope, a fine pair of tweezers and a UV radiation source, this *in vitro* selection process can be completed. The now-fluorescent antibody-peptide-resin complex is removed with the tweezers, the antibody is dissociated from the peptide resin by washing, and the peptide resin can now be sequenced directly in the protein sequencer to identify the primary structure of the unknown synthetic epitope.

This article has summarized the most significant developments in the field of automated protein sequencing since the introduction of the Edman chemistry. It is not unreasonable to expect that the next major advance in protein sequencing by the end of the 1990s and into the twenty-first century will be based on the routine use of mass spectrometry, giving

orders of magnitude increases in both speed and sensitivity of analysis (see Proteins, sequencing by mass spectrometry).

## Introduction

The differentiation and determination of proteins in body fluids is fundamental in clinical diagnosis, since qualitative and/or quantitative alteration can be linked to different disease conditions. The subject is

so vast, however, that this article has been limited largely to the analysis of serum proteins, neglecting other body fluids such as urines, cerebrospinal fluids (CSFs), tears, saliva, and sweat. It describes the most common methods of analysis, followed by a table listing (according to electrophoretic migration in agarose) of most of the presently known serum proteins with details of their relative molecular mass, reference mobility, standard concentration intervals, functions and properties, and causes of elevated and decreased levels.

## Analysis for Proteins

The methods of analysis for proteins in body fluids can be roughly grouped as follows:

1. Quantitative measurements of total proteins.
2. Separations by electrophoresis that provide semi-quantitative estimations of the main classes of proteins present in a fairly high concentration.
3. Specific quantitative assay of particular proteins by immunochemical methods using specific antisera and measurement of the antigen-antibody (Ag-Ab) complexes by nephelometry, turbidimetry, radial immunodiffusion (RID) or radioimmunoassay (RIA), or enzyme immunoassay.
4. Detection and identification of abnormal proteins by RID, immunoelectrophoresis (IE), and immunofixation electrophoresis (IFE).

### Methods for Determination of Total Proteins in Serum and Plasma

The overall protein composition of a patient's plasma or serum should be studied first in terms of its total protein content. The total protein concentration of serum in healthy adults is  $60\text{--}80\text{ g l}^{-1}$ . There are two general causes of alterations of serum total proteins: change in the volume of plasma water and change in the concentration of one or more of the specific proteins in the plasma. A decrease in the volume of plasma water (hemoconcentration), as seen in inadequate water intake or excessive water loss, results in relative hyperproteinemia. Hemodilution (increase in plasma water volume), as seen in water intoxication or salt retention syndromes during massive intravenous infusion, is reflected as relative hypoproteinemia. In these cases the concentrations of all the individual plasma proteins are increased or decreased to the same degree. Individual serum proteins may also cause an increase or decrease of total plasma protein concentration: low levels of albumin cause hypoproteinemia (very commonly and with many causes), while a mild hyperproteinemia may be

caused by an increase in the concentration of specific proteins normally present in relatively low concentration (e.g., in acute-phase reactants, polyclonal immunoglobulins, in myeloma, or other malignant paraproteinemia).

When the total protein concentration in serum is measured, two assumptions are arbitrarily made: (1) that all protein molecules are pure polypeptide chains, containing on an average 16% by weight of nitrogen (an assumption that is not true at all), and (2) that each of the several hundred individual proteins present in serum reacts chemically like every other protein (not always true). These simplifying assumptions make the measurement of total protein a practical, though empirical, procedure.

**The Kjeldahl method** This consists of acid digestion to release ammonium ions from nitrogen-containing compounds. The ammonium can then be quantified by conversion to ammonia gas and titration as a base or by Nesslerization in which mercury(II) and potassium iodide are used to form a colored species with ammonia under alkaline conditions. A correction is made for nitrogen contributed by nonprotein compounds also present in serum, and the ammonia nitrogen value is multiplied by  $100/16$  (i.e., a factor 6.25) to express protein nitrogen as total protein. While determination of nitrogen content can be extremely precise, its use for calculation of protein concentration depends on the exact protein composition of the sample, since each protein has somewhat different nitrogen content according to its amino acid composition. The methods are time consuming and not simple, so they are not commonly used in clinical laboratories. However, they remain a means of defining reference standards for the biuret method (described next).

**The biuret method** The biuret method is a colorimetric technique specific for proteins and peptides. Copper salts in alkaline solution form a purple complex with substances containing two or more peptide bonds. The absorbance produced is proportional to the number of peptide bonds that are reacting and therefore to the number of protein molecules present in the reaction system. Thus, the biuret reaction with proteins is suitable for the determination of total protein by spectrophotometry (at  $540\text{--}560\text{ nm}$ ). The method is used extensively in clinical laboratories, particularly in automated analyzers in which protein concentration can be measured down to  $0.1\text{--}0.15\text{ g l}^{-1}$ . The use of bovine or human serum albumin to standardize the biuret method is well established. High-purity albumin contains only amino acids; its nitrogen content is a constant fraction

of its molecular mass and the number of peptide bonds per molecule is known. Since the peptide bond is the biuret-reacting unit in all proteins and the number of peptide bonds determines the absorbance of the colored product, albumin is a reasonable peptide bond standard for all proteins in the mixture.

**Refractometry** Refractometry is a quick and reasonably accurate alternative to chemical analysis for serum total protein when a rapid estimate is required. The refractive index of water at 20°C is 1.330; if solute is added to the water, the refractive index of a dilute solution increases linearly and proportionally to the solute concentration; at higher concentrations of dissolved solids (50–200 g l<sup>-1</sup>), the increase is nearly linear. Temperature affects appreciably the refractive index of a solution, so refractometers for clinical use compensate for temperature effects. Serum contains dissolved solids in concentrations of 80–100 g l<sup>-1</sup>, most of which are proteins. In the refractometry of serum, it is assumed that the concentration of inorganic electrolytes and nonprotein organic compounds does not vary appreciably from serum to serum and that the differences in the refractive index reflect primarily the differences in protein concentrations. The assumption has been shown to be reliable for clear, nonpigmented samples, but hemolysis, lipemia, icterus, and azotemia produce erroneously high results. The method cannot be used for urine protein measurement because of excess solutes in relation to the protein.

**Other methods** Although other methods have been used for total serum protein quantification, none is more convenient or practical than the biuret method. These methods are reviewed here predominantly as background information for the assay of total protein in urine or CSF. They are dependent on four general properties of proteins.

1. Reaction of tyrosine and tryptophan residues with the Folin–Ciocalteu or phenol reagent (tungstophosphoric or molybdophosphoric acid) to give a deep blue color. This property is more advantageous for assaying a pure protein whose composition and relative reactivity are known (e.g., fibrinogen) than it is for a mixture of individual proteins with different concentrations and reactivities. The Lowry method uses the biuret method followed by the phenol reagent, which greatly enhances color formation since the phenol reagent can react with biuret complexes involving all the peptide bonds. The absorbance of the colored species is measured at 650–750 nm. The Lowry method is sensitive to protein at concentrations of 10–60 µg ml<sup>-1</sup>, i.e., it is 100 times more

sensitive than the biuret reaction alone. The Lowry method is widely used in research to quantify tissue proteins and enzyme proteins in purified preparations. In urine and CSF, the method is not satisfactory because the reagents react nonspecifically with nonprotein compounds. Many drugs such as salicylate, chlorpromazine, tetracyclines, and some sulfa drugs also give a positive interference. The method is not used in clinical laboratories.

2. Measurement of the characteristic UV absorbance at 280 nm ( $A_{280}$ ), which depends largely on the tryptophan and also on the tyrosine and phenylalanine content of proteins. For accurate conversion of  $A_{280}$  readings to concentration, the molar absorptivity must be used, since each protein contains different amounts of these three amino acids. However, the  $A_{280}$  value of a mixture of proteins is not an accurate measure of protein content, since molar absorptivities vary greatly between different proteins. Because nucleic acids, which absorb strongly at 260 nm, may be present in protein preparations, total protein can be estimated by the equation

$$\text{Protein concentration (mg ml}^{-1}\text{)} = 1.55A_{280} - 0.76A_{260}$$

so that absorbance can be used for quantifying proteins in the range of 0.05 – 1.5 mg ml<sup>-1</sup>. The method has been used for CSF after removal of small interfering molecules by gel filtration. This approach is sensitive and simple but requires the use of an appropriate spectrophotometer and expensive (silica) cuvettes with high transmittance at 220–280 nm.

3. Precipitation of protein for turbidimetric or nephelometric assays, which can be achieved with sulfosalicylic acid alone, sulfosalicylic acid with sodium sulfate or trichloroacetic acid, or trichloroacetic acid alone. Precipitation methods for total protein assay require that both globulins and albumin are efficiently precipitated with the formation of small, well-dispersed particles of consistent size so that light scattering is a reproducible phenomenon. The particles must be homogeneously suspended in the medium at all times. Standard material must have as nearly as possible the precipitation behavior of normal and abnormal mixtures of plasma and proteins. Specific turbidimetric precipitation methods have been described for total protein determination in urine and CSF.

4. Ability to bind colored dyes, such as Amido Black 10 B, Ponceau S, and Coomassie brilliant blue (CBB). This property is not only utilized to stain protein bands after electrophoresis but can also be used in spectrophotometric methods for total protein determination. There are two major problems: the unequal affinities and binding capacities of individual

proteins for dyes, and the inability to define a consistent material for use as a standard. The CBB method was originally described for CSF and subsequently adapted to urine. The absorbance is measured at 495 and 595 nm (bichromatic mode). The method is simple, fast, and linear up to  $1.5 \text{ g l}^{-1}$  and can be automated (coefficient of variation from run to run  $<5\%$ ). Negative interferences are noted in urine specimens with a high content of sodium chloride or hydrochloric acid used as preservative, while positive interferences are seen with tolbutamide and high concentrations of urea. The color obtained with CBB and albumin is taken as 100%. Hemoglobin and transferrin give a similar color intensity, while globulin and  $\kappa$  and  $\gamma$  chains give only 60%. For the standardization of precipitation and dye-binding methods, a suitable dilution of a normal serum (or normal serum pool) with normal albumin/globulin ratio and quantified for total protein with a reference method (biuret or Kjeldahl method) is used. The intent is to have in the standard a mixture of proteins whose precipitation and dye-binding behavior are similar to that of proteins in the sample to be analyzed. Bovine or human serum albumin as standard prohibits the use of sulfosalicylic acid because these pure proteins give  $\sim 2.5$  times the turbidity given by serum globulins. With these pure proteins, trichloroacetic acid is the reagent of choice.

## Electrophoresis

Modern understanding of protein composition derives from the electrophoretic techniques introduced by Tiselius in 1937 whereby proteins were separated in an electrolyte solution contained within a U-shaped quartz tube through which an electric current was passed. At pH 7.6, four fractions designated albumin, alpha, beta, and gamma were identified and quantified by the change in the refractive index at the boundaries between these bands. Because separation was achieved in a homogeneous solution without a solid support medium, convective forces prevented resolution into more distinct zones. Hence, this technique was termed moving-boundary or frontal electrophoresis. Separation of the protein fractions into discrete bands or zones became possible with the introduction of filter paper as an anticonvection support medium. The term 'zone electrophoresis' was introduced to refer to the migration of charged macromolecules in a porous supporting medium such as cellulose paper, cellulose acetate sheets, agarose gel film, starch gel, and polyacrylamide gel. Zone electrophoresis differs from moving-boundary

electrophoresis in that it generates an electrophoretogram, a display of protein zones, each one sharply separated from neighboring zones on the electrophoretic support material. Solutes of interest in clinical chemistry are mainly macromolecular in size and colloidal in nature, and include proteins in serum, urine, CSF, and other physiological fluids as well as the proteins in erythrocytes and tissue.

The theory of electrophoresis is discussed in detail in another article, but it must be noted here that the rate of protein migration is dependent on such factors as net electric charge of the molecule, size and shape of the molecule, electric field strength, properties of the supporting medium, and the temperature of the operation.

Buffer ions have two purposes in electrophoresis: they carry the applied current and they fix the pH at which electrophoresis is carried out and thus determine the kind of electrical charge on the solute and the extent of ionization of the solute. Through these effects the buffer determines the direction of the electrophoretic migration to one of the two electrodes. The buffer ionic strength determines the thickness of the ionic cloud surrounding the charged molecules and thus also the rate of migration and the sharpness of the zones. Many buffer systems have been used in electrophoretic procedures: the barbital buffer (ionic strength  $0.025\text{--}0.075 \text{ mol l}^{-1}$ ) and the Tris-boric acid-EDTA buffer (ionic strength  $0.03\text{--}0.12 \text{ mol l}^{-1}$ ) are common.

### High-Resolution (High-Performance) Electrophoresis

This involves modifications to conventional electrophoresis that allow resolution of normal serum proteins into as many as 13 bands: a relatively high ionic strength buffer ( $0.075 \text{ mol l}^{-1}$  at pH 8.6) mixed with calcium lactate in an  $8 \text{ g l}^{-1}$  low-electroendosmosis agarose gel is used. When an electrophoretic support medium has a negative charge, the electromotive force tends to move such a charge toward the anode. However, since the solid support medium is fixed and stationary, buffer flows toward the cathode instead. This buffer flow is termed electroosmosis or endosmosis, which also carries the proteins with it to some extent. When the electroosmotic force is greater than the electrophoretic force acting on weakly anionic proteins (e.g.,  $\gamma$ -globulins), these proteins move from the application point toward the cathode although their charge is slightly negative. Endosmosis is minimal in electrophoretic media where surface charges are minimal (starch gel or polyacrylamide gel).

### Paper Electrophoresis

Paper electrophoresis using either Whatman no. 1 or 3 MM paper or their equivalents as support medium was very common in clinical laboratories in the past, but electroendosmosis was prominent and the separation time was long (14–16 h).

### Cellulose Acetate Electrophoresis

This is widely used today. The characteristics of the membrane will vary with the extent of acetylation, the prewashing procedure employed by the manufacturer, and the additives used, as well as the pore size and the thickness of the membrane. Cellulose acetate membranes may be made transparent (cleared) for densitometry by treatment with a solvent mixture that partially dissolves the cellulose acetate fibers and eliminates the original air spaces. Advantages are the speed of separation (20 min–1 h) and the ability to store the transparent membranes for long periods.

### Agarose Gel Electrophoresis

This has been used successfully for analysis of serum proteins, hemoglobin variants, lactate dehydrogenase isoenzymes, lipoprotein fractions, etc. Agarose, which is essentially free of ionizable groups, exhibits little endosmosis. Usually 5–10 g of agarose per liter of buffer provides a gel of desired strength and with good migration properties. The serum sample size used in this kind of electrophoresis is relatively small (0.6–3  $\mu$ l) and the electrophoresis time is short (30–90 min).

### Polyacrylamide Gel Electrophoresis

Polyacrylamide is an inert support whose porosity is easily adjusted by changing the composition of the acrylamide solution prior to polymerization. Although polyacrylamide gel electrophoresis (PAGE) is applicable to standard separations of native proteins, it can also be used for separating proteins according to molecular mass when they are denatured in the presence of sodium dodecyl sulfate (SDS); hence, the term SDS PAGE. This last technique is very powerful for resolving proteins and separating them into multitudinous subunits. It is used in the clinical laboratory for highly individualized investigations (e.g., studies of proteinuria).

### Starch Gel Electrophoresis

This also possesses the property of separating macromolecular ions on the basis of both surface charge and molecular size. The starch gel is partially hydrolyzed since native starch does not gel. Proper

preparation of the gel requires considerable skill and is relatively difficult. The concentration of starch gel is generally 100–160 g l<sup>-1</sup> and the pH of the buffer is between 8.6 and 9.0.

### Isoelectric Focusing

Isoelectric focusing (IEF) affords superior resolution of closely migrating proteins or various forms of a single protein that differ in charge owing to minor modifications. With this technique proteins migrate through a gel containing a pH gradient established with a mixture of carrier ampholytes (amphoteric oligoamino–oligocarboxylic acids). As each protein reaches the gel location where the pH is equal to its pI (pH at which the protein carries zero net charge), it comes to rest. Thus, the final pattern strictly accords with the pI value of the proteins.

### Immobilized pH Gradient Electrophoresis

This is a modification of IEF in which the pH gradient is not created by the electric field but is preconstituted by covalently grafting on to a polyacrylamide matrix a series of buffering and titrant acrylamide derivatives (known commercially as immobilines).

### Emerging Techniques

While not yet active in clinical analysis, two techniques appear to be of great interest: two-dimensional (2D) maps and capillary zone electrophoresis (CZE). In 2D maps, denatured polypeptide chains are separated in two dimensions, first by surface charge (IEF) and then orthogonally by size (SDS electrophoresis). In normal human sera, for example, 600 spots are separated and detected by silver staining.

In CZE, proteins are separated in 50–100  $\mu$ m i.d. capillaries with very high resolution, and direct on-line quantification is often achieved by exploiting the absorbance of the amide bond at 210 nm.

### Staining of Protein Fractions after Electrophoresis

After electrophoretic separation, protein fractions are visualized by staining with a suitable dye. Ideally, a dye should have equal affinity for all proteins and sufficient sensitivity to detect each protein. However, the most commonly used dye for cellulose acetate separation, Ponceau S, has 1.5 times greater affinity for albumin than for  $\gamma$ -globulin. Other widely used dyes that behave in a similar manner are Amido black 10 B (Amidoschwarz 10 B), Naphthol blue black or Buffalo black, a stain commonly employed for agarose separations, and CBB, a dye widely used for agarose and polyacrylamide gel separations. In

terms of sensitivity, Ponceau S on cellulose acetate or Amido black on agarose can detect proteins whose concentrations in the sample exceed 300–500 mg l<sup>-1</sup>. CBB is slightly more sensitive and is suitable for detection of an oligoclonal band in concentrated CSF. Silver staining binds to specific amino acid groups in proteins in a manner independent of the net protein charge and can routinely detect proteins at concentrations as low as 100 mg l<sup>-1</sup>, a sensitivity some 20–50 times greater than that of CBB. Silver staining is therefore an attractive choice for CSF and any other fluids when both a low protein concentration and a small volume are available. Its disadvantage is its greater complexity. In addition, the technique is less suited for serum and other body fluids. To quantify each electrophoretic protein band, the plate may be scanned with a densitometer.

### **Immunological Methods**

The strength or energy of interaction between an antibody and an antigen is described by two terms. 'Affinity' refers to the thermodynamic quantity defining the energy of interaction of a single antibody-combining site and its corresponding epitope on the antigen. 'Avidity' refers to the overall strength of binding of antibody and antigen and includes the sum of the binding affinities of all the individual sites on the antibody. For example, immunoglobulin G (IgG) has two affinity-binding sites, whereas immunoglobulin M (IgM) has 10 affinity-binding sites per antibody molecule. Thus, affinity is a property of the substance bound (antigen) and avidity is a property of the binder (antibody). For polyclonal antibodies, avidity is difficult to determine, primarily owing to the diversity of the antibody population.

Several forces act cooperatively to produce antigen–antibody binding. The three major contributing forces are van der Waals–London dipole–dipole interaction, hydrophobic interaction, and ionic Coulombic bonding. The binding of antigen to antibody is not static but is an equilibrium reaction that proceeds in three phases. The initial reaction (phase 1) of a multivalent antigen (Ag<sub>n</sub>) and a bivalent antibody (Ab) occurs very rapidly in comparison with the subsequent growth of the complex (phase 2). The third phase of the reaction involves the precipitation of the complex after a critical size is reached. The speed of these reactions depends on factors such as electrolyte concentration, pH, and temperature, as well as on antigen and antibody types, and the binding affinity of the antibody. The concentration of sodium chloride is important: in most cases 0.15 mol l<sup>-1</sup> is used. It is best to use dilute solutions for determining the influence of such factors as ionic

species, ionic strength, pH, and concentration of soluble linear polymers, and for optical analytical methods. The use of dilute solutions slows the growth of the antigen–antibody complexes and a more stable and more homogeneous population of complexes results. If the antigen or antibody of interest is bound to a solid phase such as a cell membrane or a synthetic particle (polystyrene or cellulose), the protein will exist in a microenvironment that is different from that of a protein free in solution. The water surrounding the protein is more highly ordered near the surface of the solid phase and a condition results that is more favorable for dispersion and dipole–dipole interactions and Coulombic bonding. This situation favors the formation of low-avidity as well as high-avidity antigen–antibody complexes and hence can provide better sensitivity for analytical applications. Some studies have shown radiometric solid-phase assays to be more sensitive than their counterpart solution assays. The difference in sensitivity is most likely a result of additional low-avidity antibody binding during the initial incubation in the solid-phase system, which does not occur as readily in the liquid phase.

### **Qualitative Immunological Methods for Detecting Proteins**

**Passive gel diffusion** Many qualitative and quantitative immunochemical methods are carried out in a semisolid medium such as agar or agarose. The primary advantage in using a gelatinous medium is stabilization of the diffusion process with regard to mixing caused by vibration or convection and to allow visualization of precipitin bands for qualitative and quantitative evaluation of the reaction. Two basic approaches to passive diffusion are in common use today. In 'single' immunodiffusion a concentration gradient is established for only a single reactant. It usually depends on diffusion of an antigen into agar impregnated with antibody. A quantitative technique based on this principle is RID. 'Double' immunodiffusion in two dimensions (Ouchterlony technique) is a widely used technique in immunology. In this technique a concentration gradient is established for both reactants (antigen and antibody); it allows direct comparison of two or more test materials and provides a simple and direct method for determining whether the antigens in the test specimens are identical, cross-reactive, or nonidentical. Note that a negative reaction does not necessarily imply absence of antibody or antigen. A negative reaction can result from using amounts of material below the detection limit of the method; alternatively, the antibody may be nonprecipitating.

**Immunoelectrophoresis (IE)** This couples electrophoretic separation with the 2D immunodiffusion reaction and is used for specific identification and semiquantitative estimation of a wide range of antigens. First, the electrophoresis of a protein mixture is carried out in agar gel on a plastic or glass support, and then a trough is prepared along one margin of the slide and a specific antiserum is applied in the trough. Diffusion is then allowed to proceed overnight. In the clinical laboratory this procedure has primarily been applied to the evaluation of human myeloma proteins. However, the method has slowly been replaced by IFE.

**Crossed immunoelectrophoresis** Also known as 2D IE, this is a variation of IE in which electrophoresis is also used in the second dimension to drive the antigen into a gel containing antibodies specific for the antigens of interest. This technique is more sensitive and produces higher resolution than is possible with IE. As with IE, the specimen is applied to a cylindrical well cut in an agar medium and is then subjected to electrophoresis in the first dimension, followed by electrophoresis at 90° to the first run through the gel, which contains antibodies. Precipitation occurs along the lateral margins as the antigen advances and results in precipitation 'peaks' for each antigen. Quantities of individual antigens can be estimated by measuring the peak area of the antigen under the precipitation arc and comparing it to the peak area of a standard antigen preparation. This technique has its greatest utility in evaluation of protein mixtures in the study of protein alterations subsequent to activation or interaction with other molecules. The method was developed by Laurell and has often been referred to as the 'rocket' technique. This method closely parallels that of RID. It offers the advantage of more rapid completion of the assay owing to the enhanced migration achieved by the use of electrophoresis. One important limitation of the 'rocket' technique is that the relative net charge of macromolecules at the pH used in the test must be estimated accurately, because it will determine the direction of migration of the molecules to either the anode or cathode.

**Counter immunoelectrophoresis (CIE)** Here two parallel lines of wells are punched in the agar. One row is filled with antigen solution and the opposing row is filled with antibody solution. If the solutions were allowed to diffuse passively over the next 18–24 h, a precipitation line would form between the opposing wells where antigen reacted with specific antibody. In CIE, this process is made to occur more rapidly by applying a voltage across the gel so that the antigen and antibody move in opposite directions

as a result of electroendosmosis and a precipitation line is formed where they meet. Qualitative information (i.e., identification of antigen) is provided within 1–2 h.

**Immunofixation electrophoresis** This is a method of immunochemical identification of proteins following electrophoretic separation. It is gradually replacing IE because of its rapidity and ease of interpretation. Several procedures and commercial kits are available for IFE and IE. While these procedures may differ in detail, their principles are the same. IFE is used mainly for estimation of paraproteins. The first step consists of an estimation of the paraprotein from the spike identified on the electrophoresis plate by densitometric scan. The second step is to identify heavy and light chains by IE or more simply by immunofixation. Specific antisera against  $\gamma$ ,  $\alpha$  and  $\mu$  heavy chains and against  $\kappa$  and  $\lambda$  light chains are used; antisera against immunoglobulins IgD and IgE are seldom required. Reaction of the paraprotein with only one heavy-chain and one light-chain antiserum confirms that the anomalous spike on protein electrophoresis is indeed a paraprotein and is not due to denaturation, fibrinogen, hemoglobin, or some other artifact. Samples of the patients' specimens are placed in six wells on an agarose gel and their major protein groups are separated by electrophoresis. One of these tracks is then treated with a chemical fixative solution to fix all proteins in the agarose and create an electrophoresis reference pattern for the specimen. The other five tracks are treated with specific heavy-chain and light-chain antisera that react with individual immunoglobulins in the specimens, causing them to become immunofixed in the agarose. All unreacted proteins in these five tracks are then washed out of the gel and all six tracks are stained to visualize the fixed protein bands. By comparing the locations of the stained immunofixed bands with a band at the same location in the reference pattern, a specific protein can be identified. In monoclonal gammopathies, the IFE patterns yield a distinct, sharply defined precipitation band with one heavy chain and one light-chain antiserum. The bands match the location of the particular immunoglobulin in the reference pattern. In polyclonal gammopathies, a diffuse precipitation band will occur with the specific antiserum in contrast to the sharp band observed in monoclonal gammopathies. The method can be used for other protein identification in a similar way.

### Quantitative Methods for Measuring Proteins

**Radial immunodiffusion and electroimmunoassay (EI)** Typically, the two most commonly encountered

gel-based methods for quantitative immunochemical studies are RID and EI (the 'rocket' technique): RID is a passive diffusion method in which a concentration gradient is established for a single reactant, usually the antigen. The antibody is uniformly dispersed in the gel matrix. Antigen is allowed to diffuse from a well into the gel until the antibody is in excess and immune precipitation occurs; the antigen-antibody interaction is manifested by a well-defined ring of precipitation around the antigen well. The ring diameter will continue to increase until equilibrium is reached. Standards are run at the same time as the sample, and a standard curve of ring area or diameter versus concentration is plotted. The original procedure described by Mancini requires the establishment of equilibrium before measurement of the precipitin ring diameter. Under equilibrium conditions, there is a linear relation between antigen concentration and the square of the ring diameter.

In EI, as in RID, a single concentration gradient is established for the antigen, but in this case an applied voltage is used to drive the antigen from the application well into a homogeneous suspension of antibody in the gel. This produces, as opposed to RID, a unidirectional migration of antigen and results in increased sensitivity. The height of the resulting rocket-shaped precipitation line is proportional to the antigen concentration. Quantification is effected by using standards on the same plate.

In general, gel-based methods for quantification of antigens require excellent technical skill, as well as tedious preparation and execution, to produce good results. In many clinical laboratories these methods are restricted to qualitative studies or are used as reference methods. Quantitative data are more commonly obtained by turbidimetric and nephelometric methods, RIAs, enzyme immunoassays, and fluorimetric immunoassays.

**Turbidimetric and nephelometric assay** Nephelometry and turbidimetry, because of their speed and ease of use, are most widely used. These techniques can be used either by measuring the amount of Ag-Ab complex formation (endpoint methods) or by measuring the rate of complex formation (kinetic methods). The kinetic methods are more rapid because measurements are accomplished within 20 s, and are more precise because sample blanks are not necessary. Kinetic assays are, however, somewhat less sensitive because low-affinity antibodies do not have time to react. The occurrence of Ag-Ab formation is related to the amount of light scattering and is used as the basis for antigen quantification. This approach has been accompanied by the development of

sophisticated instruments specifically designed rapidly to measure scattered light, i.e., nephelometers. Turbidimetry, in contrast, measures the decrease in intensity of transmitted light. Nephelometry has proved useful because of its sensitivity and specificity for rapidly detecting immune complex formation. Filtered light of a certain wavelength enters the analytical cell containing a suspension of reactant material and is scattered by the immune complexes. A photomultiplier tube located at an angle of 30–90° to incident light measures the intensity of the scattered light. The sensitivity can be enhanced by using an intense light source as used in a spectrofluorimeter. Also, use of enhancing reagents such as poly(ethylene glycol) has improved the assay by increasing the speed and sensitivity of Ag-Ab formation so that measurements can be made within seconds to minutes after antigen-antibody mixing. Within the last few years, improved instruments utilizing laser and other light sources along with microcomputerized data handling to determine reaction rates for precipitate formation have appeared. Such devices offer the promise of even more rapid and sensitive assays. One limitation of this technique is that the antisera and test specimens must have low levels of intrinsic light-scattering activity. The antiserum must have high affinity and monospecificity for the assay antigen. An antiserum exhibiting these properties is referred to as 'nephelometric grade'. Those nephelometric systems that employ 'steady-state' conditions require that optimum antigen-antibody ratios be established for use in the assays. This is necessary in order to determine the dilutions of antigen and antibody that are sufficient to produce light scattering by immune complex formation but avoid rapid development of large particles that cause an uneven distortion of the light-scattering response. Once the dilutions have been determined, the antiserum is mixed to the diluted test specimen either individually, in a continuous flow system, or under conditions of constant mixing as in a rotary chemical analyzer. Once 'steady-state' conditions have developed, light-scattering measurements are made and the peak height response from the photomultiplier tube is recorded. Standards that contain known concentrations of the antigen are measured in order to obtain a calibration graph.

The methods discussed so far rely on examining immune complex formation as an index of an antigen-antibody reaction. For measuring the initial phase, i.e., the primary reaction  $\text{Ag} + \text{Ab}$ , different physical and chemical techniques are required. Many of the methods have provided important information on the mechanism of the antigen-antibody reaction but are not applicable for use in a clinical laboratory.

The following section discusses selected methods appropriate for clinical laboratory use.

**Radioimmunoassay and immunoradiometric assay (IRMA)** RIA and IRMA methods are capable of measuring the primary reaction between hapten (hapten is an incomplete antigen that cannot elicit an immune response by itself but can react with antibody of block a specific antigen-antibody complex) or antigen and a single antibody. In RIA the hapten or antigen is labeled with a radioactive isotope, whereas in IRMA the antibody is the labeled species. RIA and IRMA are concerned only with the primary combination of antigen and antibody. The two standard procedures for RIA are termed competitive and sequential. In a competitive RIA, all reactants are mixed together simultaneously. Labeled antigen (Ag) and unlabeled antigen (Ag) compete for binding to the antibody. In such a system, the avidity of the antibody for both the labeled and unlabeled Ag compete for binding to the antibody. In such a system, the avidity of the antibody for both the labeled and unlabeled antigens must be the same. Under these conditions, the probability of the antibody binding the labeled antigen is inversely proportional to the concentration of unlabeled antigen; hence, bound counts are inversely proportional to unlabeled antigen concentration. For some antisera a competitive RIA is not as sensitive as a sequential RIA, especially in cases where the antiserum has different avidities for the labeled and unlabeled antigens. In the sequential approach, unlabeled antigen is first mixed with excess of antibody and binding is allowed to achieve equilibrium. Labeled antigen is then added and allowed to equilibrate, and, after separation, the bound and free counts are determined. With this approach, a higher fraction of the unlabeled antigen can be bound by the antibody than in a competitive assay, especially at a low antigen concentration. Sequential assays can provide a two- to fourfold increase in sensitivity compared to a competitive assay.

Labeled antibody assays (IRMA) have the advantage of not requiring a quantity of purified antigen because the antigen need not be labeled. This also obviates potential problems that may arise from iodination of labile antigens. Antibodies are more stable proteins and are less difficult to label without damaging the protein's function. An IRMA often requires additional steps for addition of reactants or washing. Typically, a 'sandwich' or two-site IRMA method is used. In these systems, antibody is first attached to a solid phase by passive absorption or by using reactions that result in covalent binding of the antibody to the solid phase. IRMA is a common

approach for protein antigen measurement, owing to its simplicity and ease of application in the routine laboratory. Indirect IRMAs have also been described.

**Nonisotopic immunoassays** Use of nonisotopic immunoassays has, in the last few years, become increasingly common in both research and clinical laboratories. Although these immunoassays do not employ radioactive labels, they may have sensitivities similar to those of classic RIA. The immunochemical mechanism and principles are the same as for RIA; only the label and the method of measurement are different. The most common labels are enzymes and fluorescent conjugates, which may be covalently bound to antibodies or haptens.

Enzyme multiplied immunoassay technique (EMIT) is one example of a nonisotopic immunoassay. The EMIT system is considered a homogeneous system. A heterogeneous enzyme immunoassay technique is that of enzyme-linked immunosorbent assay. One of the reaction components is nonspecifically adsorbed to a solid phase, such as a microtiter tray or a plastic bead. One of the major goals in the design of all nonisotopic immunoassays has been to provide a homogeneous system in which no separation of bound and free antibody or antigen is necessary and, therefore, to make these assays technically easier and more rapid. The choice of an enzyme label in any nonisotopic immunoassay depends primarily on the application. Alkaline phosphatase,  $\beta$ -glucuronidase, glucose-6-phosphate dehydrogenase, and horseradish peroxidase are commonly used in both commercial and research systems.  $\beta$ -Glucuronidase and alkaline phosphatase, among other enzymes, can be used with either a colorimetric or fluorimetric substrate. A biotin-avidin system uses a biotin-labeled first antibody. Biotin can be attached to the antibody in relatively high proportion without loss of immunoreactivity by the antibody. When an avidin-conjugated label is added, a complex of Ag-Ab-biotin:avidin-label is formed. Further amplification can be achieved by a biotin:avidin:biotin linkage.

Fluorescent labeled antibody methods are being used to quantify antigen and antibodies similarly to RIA methods with comparable levels of sensitivity. The procedures require extensive purification and characterization of the fluorescent reagents, as well as special instrumentation (time-resolved fluorimeter) to decrease nonspecific background emissions while increasing specificity and sensitivity. The fluorescent antibody methods have been used for some time and have the advantages of greater availability of well-characterized standardized reagents and procedures.

**Table 1** Principal plasma proteins and properties

<i>Protein</i>	<i>Relative molecular mass</i>	<i>Mobility<sup>a</sup> (agarose pH 8.6)</i>	<i>Reference intervals (g l<sup>-1</sup>) [IU ml<sup>-1</sup>]</i>	<i>Function, properties, genetic variants (GVs)</i>	<i>Elevated in</i>	<i>Decreased in</i>
Prealbumin (thyroxine binding prealbumin) PA (TBPA)	54 980 (tetramer)	Prealbumin	0.25–0.45	Binds and transports T3, T4, RBP, vitamin A GV: molecular variants associated with familial amyloidosis	Glucocorticoids Hodgkin lymphoma Alcohol	Negative acute-phase reactant Hepatocellular disease Malnutrition Nephrotic syndrome Childhood Estrogens, pregnancy
Retinol binding protein RBP	20 960	Prealbumin d <sub>2</sub> (free)	0.03–0.06	Binds and transports retinol (vitamin A) Forms 1:1 complex with PA	Glucocorticoids Oral contraception Renal insufficiencies	Negative acute-phase reactant Hepatocellular disease Nephrotic syndrome Hyperthyroidism Inherited deficiency of vitamin A
Albumin ALB	66 460	Albumin	37–53 [93–133]	Actions: oncotic pressure, amino acid reservoir, carries small molecules GV: 20 genetic variants (bisalbuminemia); analbuminemia (congenital absence of albumin)	Dehydration Intravenous infusion	Negative acute-phase reactant Chronic inflammatory or neoplastic diseases Protein-losing syndromes and malnutrition Altered distribution in an extravascular compartment (ascites) Congenital absence
$\alpha$ -Fetoprotein AFP	66 300	$\alpha$ 1	<10 $\mu$ g l <sup>-1</sup> [<7]	Early in embryonic life this protein functions as the major serum protein, as albumin later Produced by the fetal yolk sac and then by the fetal liver	Neonatal period, pregnancy Hepatocellular carcinoma, hepatoblastoma Testicular or ovarian chorion carcinoma Carcinoma of the pancreas, gut, and lung Cirrhosis of the liver Tyrosinemia Ataxia, telangiectasia Congenital hypothyroidism In maternal serum: neuronal tube defects, anencephaly of the fetus	In maternal serum: intrauterine death, trisomy 21

$\alpha$ -1 Acid glycoprotein (orosomicold)	41 000	$\alpha$ 1	M: 0.50–1.30 F: 0.40–1.20	Has low pI 2.7–3.5 and 45% is carbohydrate Inactivation of progesterone	Acute-phase reactant Glucocorticoids (endogen/esogen)	Estrogen/pregnancy Malnutrition Severe hepatic damage
AAG				Binds lidocaine, propranolol, drugs Role in immune system Modifies platelet aggregation Polymorphism with no clinical significance	Rheumatoid arthritis Systemic lupus erythematosus Malignant neoplasm	Severe protein-losing gastroenteropathies
$\alpha$ 1-Antitrypsin AAT $\alpha$ 1 protease inhibitor $\alpha$ 1 PI	54 000	$\alpha$ 1	1.4–3.2 [59–134]	Antiprotease activity Acts against trypsin, kallikrein, urokinase, plasmin, etc., and especially against neutrophilic elastase, and collagenase GV: Significant microheterogeneity: 75 allotypes described Genotypes PI MM (produces M protein), PI ZZ, PI MZ, PI SZ, and PI MS Ability to inhibit protease is directly related to the circulating level of M protein	Estrogens/pregnancy Acute-phase reactant Hepatocellular disease	AAT congenital deficiency (neonatal respiratory distress syndrome) Pulmonary emphysema Neonatal hepatitis Juvenile cirrhosis Nephrotic syndrome Acute pancreatitis Severe hepatitis
Serum amyloid P-protein  (9.5 S $\alpha$ <sub>1</sub> glycoprotein, $\alpha$ 1-macroglobulin) SAP	233 000–308 000	$\alpha$ 1	0.035–0.075	Noted in most amyloid deposits; similar to lecithin High-affinity for polyanions, cations, and fibronectin Has pentagonal ultrastructure similar to C-reactive protein (CRP)		Hepatocellular diseases
$\alpha$ 1-Microglobulin $\alpha$ 1-M	31 000	$\alpha$ 1	0.02–0.05	Immunosuppression Binds lipophilic molecules (it is similar to retinol-binding protein and $\alpha$ 1-acid glycoprotein)	Renal insufficiency In urine: tubular proteinuria

<i>Protein</i>	<i>Relative molecular mass</i>	<i>Mobility<sup>a</sup> (agarose pH 8.6)</i>	<i>Reference intervals (g l<sup>-1</sup>) [IU ml<sup>-1</sup>]</i>	<i>Function, properties, genetic variants (GVs)</i>	<i>Elevated in</i>	<i>Decreased in</i>
$\alpha$ 1-Thiol proteinase inhibitor $\alpha$ -TPI	167 000–90 000	$\alpha$ 1 $\alpha$ 2	0.3–0.5	Inhibitor for thiol protease (cathepsins B1, C, H, L, and activated proteases by Ca <sup>2+</sup> )		Childhood
Transcobalamin I TCI	65 000	$\alpha$ 1	Traces	Binds vitamin B <sub>12</sub>	Hepatoma Polycythemia Myeloid leukemia	
$\alpha$ 1-Antichymotrypsin ( $\alpha$ 1-X-glycoprotein) $\alpha$ 1-X; AAC	68 000	$\alpha$ 1 slow Inter $\alpha$	0.3–0.6	Inhibits cathepsin G, mast cell kinase	Acute-phase reactant	Inherited deficit Childhood Nephrotic syndrome Asthma
Thyroxine-binding globulin TBG	54 000	$\alpha$ 1 Inter $\alpha$	0.01–0.03	Binds and transports T3 and T4 GV: qualitative and quantitative (X-chromosome linked)	Estrogens/pregnancy Inheritance Hepatitis B Hypothyroidism	Negative acute-phase reactant Glucocorticoids Anabolic steroids Hyperthyroidism Malnutrition Nephrotic syndrome
Transcortin Corticoid binding-globulin CBG	55 700	Inter $\alpha$	0.015–0.02	Binds and transports cortisol	Estrogens/pregnancy	Anabolic steroids Hypofunctional ovaries
Vitamin D-binding protein (GC-globulin) VDEP	50 800	Inter $\alpha$	0.2–0.55	Binds and transports vitamin D <sub>3</sub> Binds and removes actin GV: CG (more than 50 alleles)	Estrogens/pregnancy	Hepatopathies Protein-losing syndromes Childhood
Ceruloplasmin CP, CER	132 000	Inter $\alpha$	0.20–0.55 [64–176]	Copper-containing protein Oxidase activity toward many polyamine and polyphenol substrates, Fe(II) to Fe(III) Prevents and removes free-radical production in inflammatory diseases Genetic polymorphism	Acute-phase reactant Disease of reticuloendothelial system Hodgkin disease Infection or obstruction of the biliary tract Estrogens/pregnancy	Wilson disease Copper deficit Malnutrition Nephrosis Severe liver disease (particularly biliary cirrhosis) Childhood

Inter $\alpha$ trypsin inhibitor $\alpha_1$ -TI	160 000	Inter $\alpha$	0.2–0.7	Trypsin, acrosin, and secretory protease inhibitor Breaks elastase in two fragments: the smaller fragment is a high-affinity inhibitor for many serum proteases Precursor of LMW inhibitor in secretions and tissues	Inflammatory disorders Tumors Tumors	
Antithrombin III (heparinic cofactor) AT III	58 000	Inter $\alpha$	0.22–0.39 (plasma)	Thrombin, factor Xa, XII, XI, IX, kallikrein inhibitor Heparin accelerates the activity of AT III GV: qualitative and quantitative	Acute-phase reactant Anabolic steroids	Nephrotic syndrome Inherited deficit (hypercoagulability) Oral contraceptives Disseminated intravascular coagulation Venous thrombosis/pulmonary embolism
$\alpha_2$ -Macro-globulin $\alpha_2$ -M	72 500	$\alpha_2$	M:1.2–2.7 [50–113] F:1.4–3.2 [158–134]	One of the largest plasma proteins Inhibits proteases, coagulation factors, fibrinolysis, and complement Role in immunological and inflammatory processes Can bind and transport $\text{Zn}^{2+}$ Four subunits; dimeric structure GV: three polymorphic forms: system Xm	Nephrotic syndrome Hepatic synthesis Liver disease Diabetes mellitus Estrogens/pregnancy Childhood Neural tube defects Ataxia telangiectasia Down's syndrome	Fibrinolysis Disseminated intravascular coagulation Acute pancreatitis Stress Severe peptic ulcer Extracorporeal circulation
Haptoglobin Hp		$\alpha_2$	0.5–3.2	Binds free hemoglobin Prevents loss of iron Tetramer ( $2\alpha$ , $2\beta$ , chains); Hp2 forms polymers GV: qualitative and quantitative	Acute-phase reactant Glucocorticoids Hodgkin's lymphoma Bile duct obstruction Nephrotic syndrome (Hp 2-1 or 2-2) Ulcerative colitis	Intravascular hemolysis Ineffective erythropoiesis Estrogens/pregnancy Hepatocellular disease Nephrotic syndrome (Hp 1-1) Childhood
Hp 1-1	86 018		1.0–2.3			
Hp2-1	88 018 plus polymers		0.9–3.2			
Hp2-2	>20 0000 (polymers)		0.5–3.2			

*Continued*

<i>Protein</i>	<i>Relative molecular mass</i>	<i>Mobility<sup>a</sup> (agarose pH 8.6)</i>	<i>Reference intervals (g l<sup>-1</sup>) [IU ml<sup>-1</sup>]</i>	<i>Function, properties, genetic variants (GVs)</i>	<i>Elevated in</i>	<i>Decreased in</i>
2-HS glycoprotein 2-HS	50 000	$\alpha 2$	0.40–0.85	Component of bone and dentin matrix Affinity for Ca <sup>2+</sup> and Zn <sup>2+</sup> Opsonic property Inhibits cell-mediated immunity		Negative acute-phase reactant
C1 esterase-inhibitor C1 1NH ( $\alpha 1$ -neuro- amino- glycoprotein)	104 000	$\alpha 2$	0.15–0.35	Inhibits activated complement components C1r, C1s, coagulation factors and fibrinolysis, plasmin, thrombin, and kallikrein GV: quantitative and qualitative variants (some hypofunctional)	Acute-phase reactant	Inherited deficit (inherited angioedema)
C1 INA						
$\alpha 2$ -Antiplasmin $\alpha 2$ AP	65 000	$\alpha 2$	0.04–0.08	Inhibits plasmin (fibrinolysis) and kallikrein	Acute-phase reactant	Inherited deficit (hyperfibrinolysis)
Fibronectin (cold insoluble globulin) FN	440 000	$\alpha 2$ – $\beta 1$	0.25–0.4	Makes possible attachment to cell membranes Binds to fibrin (clots) and C1q (immunocomplexes) playing a role in opsonization and fibroblast adhesion	Chronic hepatitis	Negative acute-phase reactant Sepsis, shock Disseminated intravascular coagulation Acute leukemia Acute pancreatitis Inherited deficit
Transferrin (siderophilin) TRF	79 550	$\beta 1$	2.3–4.3 [80–150]	Principal plasma protein for transport of iron: 1 mg = 1.25 g Fe <sup>3+</sup> total iron binding capacity (TIBC) Unsaturated TRF is important during infections and parasitic diseases GV: more than 20 variants Polymorphism has no clinical significance except as the rare congenital defect attransferrinemia	Iron deficiency Estrogens/pregnancy	Negative acute-phase reactant Chronic inflammation Malnutrition Chronic liver diseases Protein-losing syndromes Iron overload Congenital defect attransferrinemia (severe hypochromic anemia)

Sex hormone-binding globulin ( $\beta$ steroid-binding globulin) SHBG	65 000	$\beta$ 1	M:0.001–0.012 F:0.003–0.015	Binds and transports testosterone, estriol, etc.	Estrogens/pregnancy	Anabolic steroids Thyroid hormones Growth hormones
Transcobalamin II TC II	53 900	$\beta$ 1	$> 25 \text{ ng l}^{-1}$	Binds and transports vitamin B <sub>12</sub> GV: some hypofunctional variants	Myeloproliferative disorders	Inherited deficit Childhood
Hemopexin HPX	60 000	$\beta$ 1	0.5–1.15	Binds free heme, prevents loss of iron	Estrogens/pregnancy	Severe <i>in vivo</i> hemolysis Nephrotic syndrome Childhood
$\beta$ 1 Pregnancy-associated glycoprotein SPI	90 000 (42 300)N	$\beta$ 1	$< 1 \times 10^{-6}$	Binds and transports steroid hormones Synthesized in the syncytiotrophoblast cells Concentration of SPI correlates placental weight	Pregnancy Trophoblastic diseases Malignant teratomas Twin pregnancy	Fetal distress Spontaneous abortion Placental insufficiency
C3 complement component ( $\beta$ 1-C-globulin) C3	180 000	$\beta$ 2	0.50–0.90 [0.64–1.15]	Glycoprotein Visible as a band on electrophoresis only if serum is fresh Polymer contains two subunits Classical and alternative pathways of complement activity Genetic polymorphism without clinical abnormalities	Subacute-phase reactant Biliary obstruction Immune complex diseases	Rheumatoid vasculitis Glomerulonephritis Gram-negative bacteremic shock Gram-positive bacteremia Disseminated cytomegalovirus infection Subacute bacterial endocarditis Inherited deficit (recurrent infections/childhood)
C4 complement-component ( $\beta$ 1-E globulin) C4	206 000	$\beta$ 2	0.13–0.37	Glycoprotein Not visible on cellulose acetate or agarose electrophoresis Polymer contains three subunits Classical pathway of complement activity Genetic polymorphism without clinical abnormalities	Subacute-phase reactant Estrogens/pregnancy Immune complex diseases	Systemic lupus erythematosus Subacute bacterial endocarditis Glomerulonephritis Gram-positive bacteremia Inherited angioedema Inherited deficit

## Introduction

Determination of proteins in food still poses some problems to the chemist and the biochemist. The high complexity of most food matrices in terms of compositions and the many interactions between chemically different components in food contribute to the difficulties. Furthermore, all the physical, enzymatic, and microbiological treatments involved in the transformation of animal and plant materials into food call for adapting even the most standard analytical procedures to the particular properties and peculiar requirements of a given food.

Proteins are perhaps the most sensitive indicator of food quality. This not only applies to the relevant issue of preventing food adulteration and fraud, as detected by the presence of foreign proteins or of undesired degradation products, but to the appreciation of the freshness of ingredients, of proper processing and handling, and of adequate storage. Most of these indicators may be derived from the analysis of proteins in food and of their modifications.

Also relevant is the identification and quantification of proteins (and of their derivatives) that are known to be detrimental to the health of sensitive individuals, or that – on the contrary – are claimed to be beneficial to human health. In view of the increased consumer awareness with respect to these issues, analytical

procedures have been developed to detect the presence of proteins eliciting negative physiological responses (either true food allergies or food intolerances of various origin), and that of proteins or peptides having beneficial effects on the well-being of humans.

This article does not deal with analysis of food enzymes, which may rely on tests adapted from those used in clinical biochemistry, but rather deals with that ‘silent majority’ of proteins in food, which lack the signature features making them easily recognizable with dedicated analytical techniques or by suitable activity assays.

## Methods Based on Protein Nitrogen

The determination of the nitrogen content of food samples, based on its conversion into simple nitrogen derivatives, is still useful, and remains the official method for determining the overall protein content in many countries and for most foods. Separation of (specific) proteins from other components in the sample is not required, unless the food contains appreciable amounts of nonprotein nitrogen-containing material (e.g., nucleotides). Typically, the protein content of the food is given as a percentage calculated by multiplying the determined nitrogen content by a factor that depends upon the material being investigated. Typical coefficients are 5.70 for cereal-based foods, 6.38 for meats, milk, and dairy products, or 6.25, which represents the most widely used value for generic foods.

## Introduction

Determination of proteins in food still poses some problems to the chemist and the biochemist. The high complexity of most food matrices in terms of compositions and the many interactions between chemically different components in food contribute to the difficulties. Furthermore, all the physical, enzymatic, and microbiological treatments involved in the transformation of animal and plant materials into food call for adapting even the most standard analytical procedures to the particular properties and peculiar requirements of a given food.

Proteins are perhaps the most sensitive indicator of food quality. This not only applies to the relevant issue of preventing food adulteration and fraud, as detected by the presence of foreign proteins or of undesired degradation products, but to the appreciation of the freshness of ingredients, of proper processing and handling, and of adequate storage. Most of these indicators may be derived from the analysis of proteins in food and of their modifications.

Also relevant is the identification and quantification of proteins (and of their derivatives) that are known to be detrimental to the health of sensitive individuals, or that – on the contrary – are claimed to be beneficial to human health. In view of the increased consumer awareness with respect to these issues, analytical

procedures have been developed to detect the presence of proteins eliciting negative physiological responses (either true food allergies or food intolerances of various origin), and that of proteins or peptides having beneficial effects on the well-being of humans.

This article does not deal with analysis of food enzymes, which may rely on tests adapted from those used in clinical biochemistry, but rather deals with that ‘silent majority’ of proteins in food, which lack the signature features making them easily recognizable with dedicated analytical techniques or by suitable activity assays.

## Methods Based on Protein Nitrogen

The determination of the nitrogen content of food samples, based on its conversion into simple nitrogen derivatives, is still useful, and remains the official method for determining the overall protein content in many countries and for most foods. Separation of (specific) proteins from other components in the sample is not required, unless the food contains appreciable amounts of nonprotein nitrogen-containing material (e.g., nucleotides). Typically, the protein content of the food is given as a percentage calculated by multiplying the determined nitrogen content by a factor that depends upon the material being investigated. Typical coefficients are 5.70 for cereal-based foods, 6.38 for meats, milk, and dairy products, or 6.25, which represents the most widely used value for generic foods.

There are two procedures based on total nitrogen determination:

1. The Kjeldahl conversion of amino and amide groups into ammonia, which is achieved by treating the sample with strong acids at high temperatures in the presence of a catalyst. Following alkalization of the digest, the ammonia is steam-distilled into a nonvolatile acid and titrated.
2. The oxidative conversion of sample nitrogen into  $\text{NO}_x$ , which is then reduced to a chromatographically detectable form. Analysis is typically carried out in an automated fashion along the lines of the CHN analyzers.

Both methods require minimal if any sample preparation, and extensively automated systems are available. The highly corrosive chemicals and the harsh conditions used in the Kjeldahl digestion call for appropriate fume hoods and exhaust systems, and standardization of the digestion itself may sometimes be difficult. The relatively low sensitivity and the fairly large amount of sample required are usually no problem in the food industry. As for chromatographic methods, controlled oxidative pyrolysis of food releases a number of volatile compounds that may foul the separation columns. This requires careful maintenance of the equipment, and in particular of the precolumn that guards the separation apparatus.

## **Spectrometric Methods**

Application of infrared spectroscopy to food analysis has made possible the highly automated determination of protein content in foodstuffs. Available commercial instruments allow the simultaneous determination of water, lipid, fiber, and protein content in solid or liquid samples with little if any sample preparation and impressive throughput.

Although the peptide bonds of proteins absorb at several wavelengths, low-energy electronic transitions, overtones, and combinations of stretching and bending vibrations are best evaluated in the near-infrared region ( $0.8\text{--}3\mu\text{m}$ ). Mid-infrared instruments operating in the  $3\text{--}15\mu\text{m}$  range are set to read at  $6.46\mu\text{m}$ , where the secondary amide groups of peptide bonds absorb, for protein quantification. Near-infrared spectroscopy may be used for online monitoring of processes, and has been applied to issues such as crop selection and breeding studies.

Transmission instruments are used in milk analysis, and suitable provisional standards are available for fat, protein, and lactose determination in whole milk by use of a mid-infrared instrument. Near-infrared reflectance techniques are typically used for

assessing the protein content in solid samples, such as grains and flours, although some commercial instruments operate in the transmission mode. Near-infrared instruments are marketed for specific applications, and typically come with sets of selective filters that allow online determination of the required parameters.

The possibility of direct and online evaluation of nutritionally relevant compounds by mathematical treatment of spectral data, and the possibility of predicting properties of the sample that are relevant for further processing make extending the applications of these techniques to food protein analysis particularly appealing.

## **Methods Based on Amino Acid Analysis**

Amino acid analysis is a very useful tool in the analysis of food since it not only allows an accurate evaluation of the amount of protein in the sample but also provides valuable information on the quality of the food under investigation, in particular as for the content in nutritionally relevant amino acids. Further information on the quality of the investigated food may be derived from the determination of specific amino acids or amino acid derivatives that are recognized as markers of improper processing or storage.

Although the direct spectrometric determination of certain amino acids in food by derivative spectrometry in appropriate spectral regions or by specific reaction with suitable reagents after unfolding of the protein structure has been attempted, amino acid analysis typically requires hydrolysis of the proteins followed by separation of the liberated amino acids.

Liquid chromatography determination of amino acids relies on procedures based either on precolumn or postcolumn derivatization. A variety of reagents and detectors are available for postcolumn derivatization, whereas the choice is somewhat more limited as for precolumn derivatization. Sensitivity, repeatability, and accuracy are extremely good with either procedure. Available commercial instruments have detection limits in the picomole range.

In the particular case of foodstuffs, problems may arise from the presence of other food components, such as some lipids, reducing sugars, and phenolic compounds, which may form derivatives resulting in altered quantification. For problem samples, the use of internal standards added prior to hydrolysis is highly recommended.

Amino acid analysis is widely used for detecting adulteration, improper processing, or fraud. Some

amino acids are typical of certain proteins, in most cases as a consequence of protein-specific post-translational modifications. Well-known examples include 1- and 3-methylhistidine in muscle proteins, and the hydroxylated forms of lysine and proline in proteins from the connective tissue. Comparison with suitable standards can detect the addition of foreign proteins to meat-based foods or the use of lesser quality materials in high-quality formulae. Another possibility is the detection of amino acid derivatives that are formed as a consequence of extreme processing conditions or of the addition of stabilizing agents. High temperatures and extreme pH values in food processing or in food sanitization leads to a number of alterations in the amino acid structure. L-Amino acids can isomerize to the D-form; they can react with other amino acids or with their decomposition products to decrease the nutritional value of food (as exemplified by the formation of dehydroalanine from cysteine, and of lysinoalanine); they can react with other food components (sugars, in most cases) to form adducts that subsequently rearrange into stable products. Also of interest for food quality are the products of de-amination or de-carboxylation reactions, which modify amino acids yielding compounds that – besides their significance as markers of food spoilage – are also physiologically active. These products include biogenic amines (from decarboxylation) and some neurotransmitters (from de-amination).

In this frame, special procedures have been devised for the detection and quantification of specific products, including the development of fast and reliable liquid chromatography–mass spectrometry (LC–MS) methods that are also suitable for detecting multiple and simultaneous reactions at different amino acid side chains. These dedicated procedures are advantageous in that they may not involve the complete and time-consuming routine of hydrolysis and chromatography, but special attention must be paid to the standardization of the procedures, and to the presence of interfering materials.

## Methods Based on Mass Spectrometry

The development of dedicated methodologies, instrumental progresses, and the ever-improving quality/price ratio for mass spectrometers due to the increasing popularity of the technique is increasing the relevance of mass spectrometry in food protein analysis. Although application of the many variations of mass spectrometric techniques to food analysis is still under development and mass spectrometry labs dedicated to food analysis are not common, this could be the technique of choice when the analytical

requirements are too challenging for more established, common, and instrumentally cheaper procedures. In principle, the sensitivity of a mass spectrometer for protein molecules is in the  $10^{-15}$  mol range, by far superior to any other available detection method. A major methodological breakthrough has been the combination of high-resolution separation techniques such as two-dimensional electrophoresis or capillary reverse-phase high-performance liquid chromatography (HPLC) ionization with mass spectrometric analysis, which is termed as the ‘proteomic’ analysis.

Electrospray mass spectrometry (ES–MS) or matrix-assisted laser desorption/ionization mass spectrometry (MALDI–MS) analysis can be used for determining the molecular weight of peptides and proteins. The accuracy of ES–MS for measuring molecular weight is impressive, as the standard deviation for routine measurements is represented by a mass shift falling within the range 2–3 Da for proteins up to 100 kDa. At the same time, MALDI-MS has complementary advantages over ES–MS, particularly when analyzing proteins with a mass greater than 100 000. The mass spectrometer can not only directly provide information on the mass of a particular peptide but can also be used to generate *de novo* amino acid sequence information, including post-translational modifications, from tandem mass spectra obtained either by postsource decay or by collision-induced dissociation (see **Figure 1**).

Also very interesting is the possibility of detecting process- or storage-induced modifications, and to monitor fundamental events that affect the structure and composition of proteins in the food industry, all in a single experiment and from minute amounts of sample. Estimating the extent and assessing the products of enzymatic or microbial proteolysis, and of process-induced modifications of food proteins (including the formation of isopeptide bonds by enzyme action or by harsh treatments) to whole food samples are some examples of how the straightforward applications of mass spectrometry may simplify food protein analysis.

## Applications of Electrophoresis and Chromatography to Food Proteins

Separative methods are advantageous in that they offer both qualitative and quantitative information, and therefore are the most powerful discriminating tool when it comes to identifying and quantifying the presence of particular proteins in food.

Application of standard HPLC procedures, based on various principles, to the separation, identification, and quantification of individual food proteins is

**Figure 1** LC-ES-MS chromatograms of the gliadin fraction from a mixture of wheat varieties. Gliadins were extracted from wheat in ethanol 70%, and directly analyzed by LC-ES-MS. (Courtesy of Prof. Pasquale Ferranti.)

often complicated by several factors, which may include: the limited solubility of many food proteins; the intrinsic heterogeneity of some proteins (as a consequence of post-transcriptional or post-translational modifications); and the occurrence of covalent and noncovalent modifications upon processing, and of hydrolytic processes during storage or ripening.

Solubility problems have been overcome by the use of denaturing agents, also in combination with reducing agents acting on disulfide bonds. This makes possible the quantitative chromatographic analysis of individual protein components also in complex systems, such as casein micelles in milk and the storage proteins in cereals and legumes. The development of specific separation protocols and the increasing use of LC-MS has changed the situation as for protein microheterogeneity, which represented a drawback for conventional methods, but is now exploited to detect subtle variations in the starting material or induced by processing/storage conditions.

Electrophoretic techniques are also highly popular in protein food analysis. Polyacrylamide gel-based separation, either depending on the protein size in denaturing conditions or on its charge in specific solvent systems (as exemplified by those used for analysis of cereal proteins), is still highly popular because of their good sensitivity, ease of use, and capability to compare a relatively large number of samples on the same gel. This unique combination of features makes electrophoresis a popular choice also from an economic standpoint.

The high resolving power of isoelectric focusing (IEF) also has been thoroughly exploited in food analysis, in particular after immobilized pH gradients have become commonplace. Again, uncharged denaturants or nonionic detergents help in tackling most of the solubility issues, which are of particular relevance in IEF. Image analysis tools and the remarkable progresses in bioinformatics in relation to proteomics was advantageous to the application of gel-based electrophoretic techniques to food proteins. The introduction of the sensitive staining technique – such as the many types of silver and gold staining – has brought the detection limits of polyacrylamide-based electrophoresis to sub-nanogram quantities of protein (see **Figure 2**).

As of this date, in spite of its high resolving power and of extensive experimentation, the application of capillary electrophoresis to food protein analysis has not gained wide recognition, at least at the level of official or recommended methods, although this separation technique offers several advantages over conventional electrophoresis in terms of sensitivity (detection of  $10^{-10}$  g protein has been reported) and speed of operation (see **Figure 3**).

One of the major drawbacks of separation techniques when applied to food protein analysis is the availability of protein standards of suitable high quality. Commercial highly purified proteins are very often a mixture of microheterogeneous proteins, so that individual laboratories may have to rely on in-house prepared standards, and complications ensue at the validation level.

**Figure 2** IEF of milk from different goat breeds. It was performed in an immobilized pH gradient (pH 2.5–6.5) in the presence of  $8 \text{ mol l}^{-1}$  urea and  $1 \text{ mmol l}^{-1}$  dithiothreitol. Rightmost lane is goat milk whey proteins isolated by ultracentrifugation. Proteins are identified on the right side. (Courtesy of Dr Maria Feligini.)

**Figure 3** Time course of protein hydrolysis in the ripening of soft Italian cheese. SDS-PAGE was performed under reducing conditions on defatted, homogenized cheese samples. Age of cheese (days after brine) is given for each sample lane. M, molecular mass markers (two different sets).

Separation techniques allow further characterization of the isolated species. Peaks from chromatographic and capillary electrophoresis runs may be collected, and electrophoretic bands on gels may be excised or blotted onto suitable membranes. Then, more powerful and sensitive techniques may be used for absolute sample identification or for the detection of specific local modifications. Common examples of these postseparative techniques include: MS or LC-MS analysis and chemical or MS sequencing of the intact protein or of its enzymatic digests; immunochemical recognition of native or modified protein

regions; and identification of nonprotein constituents by suitable chemical or spectroscopic methodologies.

## Immunological Methods

Immunological methods in food analysis offer the intrinsic advantage of very high sensitivity and specificity, and of ease of automation. However, interferences from the complex food matrices and the requirement for sample preparation steps contribute to make their application to food analysis less straightforward than in other analytical fields.

Most food proteins are excellent antigens both in their native form and in the denatured form that is often isolated from separation procedures. This makes it relatively easy to raise suitable antibodies in any of the animal species commonly used for this purpose. A relatively large number of antibodies against food proteins are readily available commercially, as are several antibody conjugates useful for quantitative and semiquantitative analysis.

Techniques used for the detection and quantification of food proteins can be divided into purely immunological techniques and techniques that combine the specificity of detection by appropriate antibodies with separation method.

The most widely used immunological approaches are those based on enzyme-conjugated antibodies, offered as “kits” that allow immunochemical detection of allergens and toxic components in foods. These products are popular in that they offer ease of automation, the possibility of analyzing a large number of samples in a single approach, besides relying on safe chemicals and simple protocols. Either direct or competitive enzyme-linked immunosorbent assay

**Figure 4** Reduction of immunoreactivity upon digestion of casein with different proteases. Competitive ELISA was performed by using polyclonal anti-casein rabbit antibodies on sodium caseinate before (dots) and after controlled digestion with a protease of pancreatic (triangles) or bacterial origin (squares).

(ELISA) formats are commonly used, depending on the nature of the coating originally placed in the microplate wells and on the nature of the conjugate used for the final detection. These techniques offer high sensitivity (detection of sub-nanogram amounts is commonplace) and relatively fast responses, and in most cases do not require sample preparation steps (see Figure 4).

When sample preparation steps are required, caution must be exercised with respect to the fact that very often they have been designed for a specific food, and therefore are not directly transferable to another food matrix. Careful preliminary experimentation and use of internal standards are mandatory when adapting to a specific food (or to food processed in a different way) a procedure originally designed for some other food. Indeed, protein antigens in processed food may become hidden as a consequence of the structural and chemical modifications induced by the severe physical treatments. These modifications can affect both the protein antigen itself and, more commonly, the surrounding matrix, in such a way that accessing the protein of interest becomes difficult. Examples of these difficulties include foods with high starch or high fat content, where preliminary enzymatic hydrolysis of the nonprotein matrix may be required for proper quantification of some protein species. Modifications of the protein itself are particularly difficult to deal with, in particular when monoclonal antibodies are used. Epitope-specific monoclonal antibodies have a great deal to offer in terms of selectivity and specificity, but the regions they recognize sometimes

may be lost in the treatments used for food processing and preservation.

Combining the specificity of antibody recognition with protein separation techniques, mostly electrophoretic ones, offers obvious advantages, which are most often exploited at the level of research and development studies. Specialized procedures such as rocket electrophoresis and variations thereof are no longer used, mostly because of the large amounts of antibodies they require. Western Blotting has become the most popular methodology: proteins are separated electrophoretically (by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), IEF, etc.), and protein bands are then transferred onto a hydrophobic membrane (nitrocellulose, polyvinylidene fluoride (PVDF), etc.). Unspecific binding sites on the membrane are blocked with an inert protein, and the analyte on the membrane is reacted with a suitable primary antibody. The antigen-antibody complex remaining after washing is then detected by a conveniently labeled secondary antibody. These methods have been used extensively for the detection and quantification of foreign proteins in materials derived from a single major commodity, and to a lesser extent to assist with establishing the pattern of sensitivity of a given individual to the different proteins in a given food. In this latter case, the serum from the patient is used as the primary antibody. Limitations of these techniques in the analysis of food proteins are related to the difficulties encountered in the electrophoretic separation of small peptides (such as those originating from proteolytic ripening processes), and to the cross-reactivity toward different protein antigens that may occur in some antibody preparations (in particular when unfractionated sera are used).

## Protein Denaturation and Interaction with Other Food Components

Treatments used in food processing may modify the native structure of proteins independently of or in concomitance with chemical/enzymatic modification of the amino acids in their primary structure. In most cases, such structural changes are a highly desirable result of processing, and process conditions are chosen that result in extensive (but controlled) protein denaturation and in the exposure of reactive functional groups. In many other cases, however, protein denaturation represents a major drawback, in that it may alter the nutritional and functional properties of the processed material.

From a chemical standpoint, there are two major classes of modifications involving proteins: those leading to the disruption or formation of new covalent

bonds and those that involve only intrinsically weak intramolecular or intermolecular interactions.

From a structural/functional standpoint, modification of a protein is reflected in changes in its aggregation state and in its surface properties. Changes in the aggregation state lead to changes in solubility and in network-forming capability, and in the sensitivity to proteolytic action as a consequence of modified exposure of the protein regions where proteases may act. Changes in the surface properties of proteins affect their emulsifying and foaming properties, and their ability to bind hydrophobic molecules or surfaces. These changes are often exploited by the food technologist, provided that they be controlled and used for specific goals. For these reasons, much effort has been dedicated to understanding and quantifying the denaturation of food proteins, and also in the general frame of all those modifications that affect the quality of a protein-based food and that are generally described as 'process damage'. Evaluating the extent of this damage, both in kinetic and in end-point studies, has provided some insights as for optimizing processes by minimizing nutritionally and technologically relevant modifications. These studies have been applied to edible fluids (milk and eggs, for instance), but are currently being extended to dry and semi-dry foods (see Figure 5).

Modifications ensuing from the formation of novel covalent bonds in food proteins include: (1) intra- and intermolecular formation of isopeptide bonds (also as a consequence of the use of transglutaminase

for improving the rheological properties of food); (2) formation of dehydroalanine from cysteine or serine residues, possibly followed by condensation of dehydroalanine with other amino acids (most notably, lysine) or with other food components; (3) Maillard-type reactions between amino acids and carbohydrates; and (4) intermolecular or intramolecular disulfide exchange. Several analytical techniques can detect these modifications. Formation of isopeptide bonds may be detected from the modified chromatographic and MS patterns in enzymatically hydrolyzed proteins, and the nature of the involved residues may be detected by MS. Chromatographic techniques, alone or in combination with MS, can monitor the formation of lysinoalanine, lanthionine, and of other condensation products between dehydroalanine and amino acids, as well as of condensation products between amino acids and sugars, such as furosine, which are recognized as markers of the intensity of thermal processing in milk and cereal-based foods. Maillard-type reactions can be monitored by the formation of their colored products, which can be detected by surface or immersion luminometry (such as tristimulus colorimetry) or by image analysis. Disulfide exchange leads to changes in the aggregation state of proteins, which can be detected by size-based separation under denaturing (but not reducing) conditions or, when extensive, by changes in protein solubility (see Figure 6).

Changes in the aggregation state may result in insolubilization of the protein, or its binding (not necessarily through covalent bonds) to other insoluble components. Thus, disappearance of a specific protein from the pool of soluble proteins in a given food may be detected by any of the techniques discussed above, and taken as a reliable index of process damage. A prime example of this simple approach to defining food quality at the molecular level may be the detection of individual whey proteins to define the quality of heat-treated milk.

However, protein insolubilization is often the final event in a sequence of modifications that involve all the levels of protein structural organization. For this reason, the mechanism of food protein denaturation is now the focus of research efforts aimed at defining the properties of the transient intermediates formed during processes and evolving into different final products as a consequence of their properties and of the kinetics of their formation. This approach opens new perspectives for modeling purposes and for directing the whole process toward the desired products. The approaches used in these studies are taken from structural biochemistry and physical chemistry, or combine protein chemistry approaches with others (such as calorimetric techniques) better suited for describing changes in

**Figure 5** Detection of disulfide-linked aggregates in pressure-treated  $\beta$ -lactoglobulin by SDS-PAGE separation under non-reducing conditions. Protein was incubated for 10 min at 37°C at 0.1 (native) or 600 MPa (pressure treated). M, molecular mass markers.

Solutions of  $\beta$ -lactoglobulin ( $3.8 \text{ mg ml}^{-1}$ ) in  $50 \text{ mmol l}^{-1}$  phosphate, pH 6.8, were heated for 15 min at the temperatures given in the figure ( $^{\circ}\text{C}$ ). Aliquots of the clear solutions of the heated protein were run on a Superdex column in  $50 \text{ mmol l}^{-1}$  phosphate,  $0.1 \text{ mol l}^{-1}$  NaCl, pH 7.0.

other food components that are interacting with the protein system under investigation.

## Examples of Determination of Specific Proteins in Processed Foods

### Immunochemical Detection of Gliadins and Gluten

Celiac disease represents an autoimmune disease associated with the consumption of gluten. Gluten represents the main water-insoluble protein fraction in several cereals, such as wheat, rye, barley, and triticale. Celiac individuals must absolutely follow a gluten-free diet, also in consideration of the fact that assumption of gluten has additive effects. However, successful implementation of a gluten-free diet is complicated by the frequent use of gluten-containing

grains, especially wheat, and of their derivatives in numerous food products, either alone or associated with other food ingredients. CODEX has established a 100 ppm limit for gluten content in gluten-free products, although the allowed daily intake of gluten in celiac patients is still much debated.

Analysis of gliadins ( $\sim 50\%$  of gluten proteins) is most conveniently carried out by immunochemical ELISA tests that all call for an initial step in which water-insoluble gliadins are extracted into aqueous ethanol (40–70% v/v). This step represents the main critical point of the procedure since the solubility of gliadins may be affected by any of the technological processes used for food production. In this frame, proper protocols for gliadin extraction are developed according to the particular food matrix.

ELISA gluten tests are also prone to interference from other food components. For example, a tannin-binding additive should be used for cocoa-based food to ensure that the detection of gluten is not inhibited. The detection of gluten in highly viscous samples of syrups obtained from starch hydrolysis is also difficult. Both the high amount of sugars in the sample and small residues of polysaccharides in the ethanolic gliadin extract result in heavy interference in the ELISA test. In this case, procedures other than sample dilution (such as sugar hydrolysis and removal) must be performed in order to reduce the glucose content to levels where it no longer interferes with the assay, while avoiding gliadin losses due to insolubilization or adhesion to the surfaces of the equipment.

### Detection of Modified Egg White Proteins

Ovalbumin is the major protein component of egg white, which represents 45% of the total proteins. As eggs age, or upon thermal treatment such as pasteurization of egg white, native ovalbumin is converted into a de-aminated form, known as S-ovalbumin. This event has obvious meanings, and is one of the many suggested markers of egg freshness, in particular when processed eggs are analyzed. However, since the denaturation temperature of S-ovalbumin is  $\sim 23^{\circ}\text{C}$  higher than that of the native protein, this conversion is also of practical relevance in that it may affect processing conditions for various egg-based products.

Detection of these ovalbumin isoforms is made difficult by the simultaneous occurrence of different glycosylated forms of the protein, which complicate the application of common and powerful separation techniques, such as reverse-phase HPLC or electrophoresis. Glycosylation not only affects the migration or elution patterns, it also makes difficult the

quantitation of the different isoforms by the common staining procedures used in electrophoresis, which are all affected to some extent by protein glycosylation.

For these reasons, methods for quantitative detection are based on ion-exchange chromatography, which exploits the charge difference stemming from de-amidation and allow easy resolution of the two ovalbumin isoforms on a suitable anion exchanger by applying a simple salt gradient in a total analysis time of 20 min. This compares favorably in terms of analysis time and amount of sample with other suggested procedures for detection of S-ovalbumin, such as those involving the use of thermal analysis techniques (differential scanning calorimetry, in this case) for discriminating protein isoforms with a different temperature sensitivity and for quantitating the enthalpy changes (and thus the protein amounts) associated with each protein species.

## Introduction

Proteomics is a rapidly growing area of molecular biology that is concerned with the systematic, large-scale analysis of proteins. It is based on the concept of the proteome as a complete set of proteins produced by a given cell or organism under a defined set of conditions. Proteins are directly involved in almost every biological process, so a comprehensive analysis of the proteins in the cell provides a unique global perspective on how these molecules interact and cooperate to create and maintain a working biological system. The cell responds to internal and external changes by regulating the level and activity of its proteins, so changes in the proteome, either qualitative or quantitative, provide a snapshot of the cell in action. The proteome is a complex and dynamic entity that can be defined in terms of the sequence, structure, abundance, localization, modification, interaction, and biochemical function of each of its components, providing a rich and varied source of data. The analysis of these various properties of the proteome requires an equally diverse range

of technologies. Proteomics provides a much more robust and representative picture of the functioning cell than other forms of large-scale biology, such as the sequencing of genomes or the global analysis of gene expression. The reasons for this are summarized in Table 1.

## Protein Separation

The analysis of proteins, whether on a small or large scale, requires methods for the separation of protein mixtures into their individual components. Protein separation methods can be placed on a sliding scale from fully selective to fully nonselective. Selective methods aim to isolate 'individual proteins' from a mixture usually by exploiting very specific properties such as their binding specificity or biochemical function. In contrast, nonselective separation methods aim to take a complex protein mixture and fractionate it in such a manner that all the individual proteins, or at least a substantial subfraction, are available for further analysis. Such methods lie at the heart of proteomics and exploit very general properties of proteins, such as their mass or net charge.

Many techniques can be used to separate complex protein mixtures in what at least approaches a

quantitation of the different isoforms by the common staining procedures used in electrophoresis, which are all affected to some extent by protein glycosylation.

For these reasons, methods for quantitative detection are based on ion-exchange chromatography, which exploits the charge difference stemming from de-amidation and allow easy resolution of the two ovalbumin isoforms on a suitable anion exchanger by applying a simple salt gradient in a total analysis time of 20 min. This compares favorably in terms of analysis time and amount of sample with other suggested procedures for detection of S-ovalbumin, such as those involving the use of thermal analysis techniques (differential scanning calorimetry, in this case) for discriminating protein isoforms with a different temperature sensitivity and for quantitating the enthalpy changes (and thus the protein amounts) associated with each protein species.

## Introduction

Proteomics is a rapidly growing area of molecular biology that is concerned with the systematic, large-scale analysis of proteins. It is based on the concept of the proteome as a complete set of proteins produced by a given cell or organism under a defined set of conditions. Proteins are directly involved in almost every biological process, so a comprehensive analysis of the proteins in the cell provides a unique global perspective on how these molecules interact and cooperate to create and maintain a working biological system. The cell responds to internal and external changes by regulating the level and activity of its proteins, so changes in the proteome, either qualitative or quantitative, provide a snapshot of the cell in action. The proteome is a complex and dynamic entity that can be defined in terms of the sequence, structure, abundance, localization, modification, interaction, and biochemical function of each of its components, providing a rich and varied source of data. The analysis of these various properties of the proteome requires an equally diverse range

of technologies. Proteomics provides a much more robust and representative picture of the functioning cell than other forms of large-scale biology, such as the sequencing of genomes or the global analysis of gene expression. The reasons for this are summarized in Table 1.

## Protein Separation

The analysis of proteins, whether on a small or large scale, requires methods for the separation of protein mixtures into their individual components. Protein separation methods can be placed on a sliding scale from fully selective to fully nonselective. Selective methods aim to isolate 'individual proteins' from a mixture usually by exploiting very specific properties such as their binding specificity or biochemical function. In contrast, nonselective separation methods aim to take a complex protein mixture and fractionate it in such a manner that all the individual proteins, or at least a substantial subfraction, are available for further analysis. Such methods lie at the heart of proteomics and exploit very general properties of proteins, such as their mass or net charge.

Many techniques can be used to separate complex protein mixtures in what at least approaches a

**Table 1** The unique position of proteomics in relation to other areas of large-scale biology

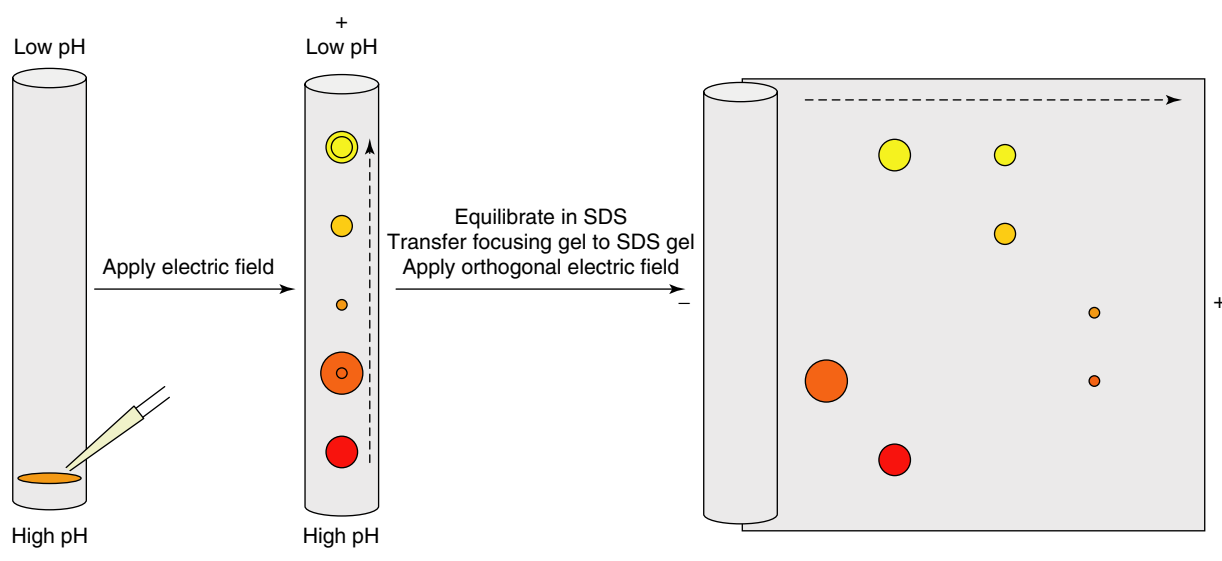

<i>Principle</i>	<i>Explanation</i>
The function of a protein depends on its structure and interactions, neither of which can be predicted accurately based on sequence information alone	Only by looking at the structure and interactions of the protein directly can definitive functional information be obtained
The abundance of a given transcript may not reflect the abundance of the corresponding protein	Messenger RNA analysis tells us the relative abundance of a transcript in the cell, and from this we infer the abundance of the corresponding protein. However, the two may not be related because of post-transcriptional gene regulation. Not all the mRNAs in the cell are translated, and rates of protein synthesis and protein turnover differ among transcripts
Protein diversity is generated post-transcriptionally	Many genes, particularly in eukaryote systems, give rise to multiple transcripts by alternative splicing. In some cases, the same transcript may give rise to multiple proteins whose individual functions cannot be studied other than at the protein level
Protein activity often depends on post-translational modifications, which are not predictable from the level of the corresponding transcript	Many proteins are present in the cell as inert molecules, which need to be activated by processes such as proteolytic cleavage or phosphorylation. In cases where variations in the abundance of a specific post-translational variant are significant, this means that only proteomics provides the information required in establishing a link between gene expression and function
The function of a protein often depends on its localization	While there are some examples of mRNA localization in the cell, particularly in early development, most trafficking of gene products occurs at the protein level. Many proteins are shuttled between compartments (e.g., the cytosol and the nucleus) as a form of regulation. In many cases, it is the distribution of a protein rather than its absolute abundance that is important
Some biological samples do not contain nucleic acids	One practical reason for studying the proteome is that many important samples do not contain nucleic acids. Most body fluids, including serum, cerebrospinal fluid, and urine, fall into this category
Proteins are the most therapeutically relevant molecules in the body	Although there has been recent development of drugs that target nucleic acids, most therapeutic targets are proteins and this is likely to remain so in the near future

nonselective fashion, but not all of these techniques are suitable for proteomics. One major requirement is high resolution. The separation technique should produce fractions that comprise very simple mixtures of proteins, and ideally each fraction should contain an individual protein. This essentially rules out one-dimensional techniques, i.e., those that exploit a single chemical or physical property as the basis for separation, since this simply does not provide enough resolving power. Proteomic techniques are therefore multidimensional, i.e., two or more different fractionation principles are employed one after another. The other major requirement in proteomics is high throughput. The separation technique should resolve all the proteins in one experiment and should ideally be easy to automate. The most suitable methods for automation are those that rely on 'differential rates of migration' to produce fractions that can be displayed or collected, a process generally described as separative transport. A final requirement is that the fractionation procedure should be compatible with downstream analysis by mass spectrometry (MS), as this is the major technology platform for high-throughput protein identification. The two groups of techniques that have come to dominate proteomics are two-dimensional gel electrophoresis (2DGE) and multidimensional liquid chromatography (LC).

## Two-Dimensional Gel Electrophoresis

In 2DGE, proteins are separated by two rounds of electrophoresis, in orthogonal directions, according to different separative principles (**Figure 1**). The first dimension separation in 2DGE is usually isoelectric focusing (IEF), in which proteins are separated based on their net charge irrespective of their mass. The underlying principle is that electrophoresis is carried out in a pH gradient, allowing each protein to migrate to its isoelectric point, i.e., the point at which its *pI* value is equivalent to the surrounding pH and its net charge is zero. Proteins with different *pI* values therefore focus at different positions in the pH gradient.

The pH gradient in an IEF gel can be established in two ways. The first is to use synthetic carrier ampholytes, which are collections of small amphoteric molecules with *pI* values corresponding to a given pH range. There are several problems with the use of ampholytes, and these lead to poor reproducibility in 2DGE experiments. One of the most serious limitations is cathodic drift, where the ampholytes themselves migrate to the cathode due to a phenomenon called electroosmotic flow (bulk solvent movement toward the cathode). This results in pH gradient instability, as basic ampholytes are progressively lost from the system. In practical terms, it is difficult to

**Figure 1** Two-dimensional electrophoresis using a tube gel for isoelectric focusing and a slab gel for SDS-PAGE. The proteins are separated in the first dimension on the basis of charge and in the second dimension on the basis of molecular mass. The circles represent proteins, with shading to indicate protein pI values and diameters representing molecular mass. The dotted line shows the direction of separation. (Reproduced with permission from Twyman RM (2004) *Principles of Proteomics*. Abingdon, UK: Bios/Garland Publishers.)

maintain a pH gradient that extends far beyond pH 7–8, resulting in the loss of many basic proteins.

These problems have been addressed by the development of immobilized pH gradient (IPG) gels, in which the buffering groups are attached to the polyacrylamide matrix of the gel. This is now the standard approach in proteomics, where reproducibility is a key issue. The IPG is established using immobilines, a collection of nonamphoteric molecules that contain a weak acid or base buffering group at one end, and an acrylic double bond to facilitate the immobilization reaction at the other. These chemicals are available from Amersham Pharmacia Biotech. The gel is run in the normal way but the pH gradient exists before the electric field is applied, and remains stable even when the gel is run for a long time. When the sample is loaded, the proteins migrate to their isoelectric points as in conventional IEF.

The second dimension separation in 2DGE is generally carried out by standard sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS-PAGE), and separates the proteins according to molecular mass irrespective of charge. The basis of the technique is the exposure of denatured proteins to the detergent SDS, which binds stoichiometrically to the polypeptide backbone and carries a large negative charge. The presence of tens or hundreds of SDS molecules on each polypeptide dwarfs any intrinsic charge carried by the proteins themselves, and stoichiometric binding means that larger proteins bind

more SDS than smaller proteins. This has two important consequences that ensure separation on the basis of mass alone. First, all protein–SDS complexes have essentially the same charge density, and second, the relative differences in mass between proteins are maintained in the protein–SDS complexes. The gel enhances the size-dependent separation by sieving the proteins as they migrate.

Today's standard 2DGE systems, which are based on first dimension IEF using IPG strips followed by second dimension SDS-PAGE, are capable of resolving ~2500 protein spots on a routine basis. However, the proteome of a complex eukaryotic cell may be more than an order of magnitude greater than this. Even in the case of a simple eukaryotic system such as yeast, where alternative splicing and post-translational protein modifications are the exception rather than the rule, individual protein spots on standard 2D gels may comprise several different comigrating proteins, which can make downstream analysis very complex. The resolution of 2DGE depends on the separation length in both dimensions, and can thus be increased if very large format gels are used. For example, IEF tube gels and IPG strips > 30 cm in length have been used to achieve maximal separation in the first dimension, in combination with very large SDS gels that also provide a separation distance of > 30 cm. Although such gels can be difficult to handle, they do allow the separation of up to 10 000 protein spots. Another way to increase the

resolution of 2DGE is to use multiple IEF gels, each with a narrow pH range. These are known as zoom gels. Following second dimension SDS-PAGE and image analysis, the images of the separate zoom gels can be stitched together by computer to produce a composite of the entire proteome. Alternatively, to increase the resolution of proteins within a particular pH range, gels with nonlinear pH gradients can be produced. This is achieved simply by increasing the spacing between the appropriate immobilized reagents, and is often used to 'flatten' the pH gradient between pH 4 and 7, which accounts for the majority of proteins in the proteome. Finally, resolution can be increased by various forms of prefractionation prior to electrophoresis, to simplify the protein mixture that is being analyzed.

The data produced by 2DGE experiments are visual in nature, so downstream analysis involves capturing the images from stained 2D gels and then isolating particular spots for further processing and MS. This process is difficult to automate and therefore constitutes the most significant bottleneck in proteomic research. Until quite recently, manual analysis and spot picking from gels was very common. However, there are now various software packages available that produce high quality digitized gel images and incorporate methods to evaluate quantitative differences between spots on different gels. These can be integrated with spot excision robots that use plastic or steel picking tips to transfer gel slices to microtiter plates for automated digestion, cleanup, concentration, and transfer to the mass spectrometer. Several commercially available systems can fully automate the analysis and processing of 2D gels, and can handle 200–300 protein spots per hour.

### Multidimensional Liquid Chromatography

In proteomics, LC has several advantages over 2DGE as a separation method, including its versatility, sensitivity, and the ease with which it can be automated and integrated with downstream analysis by MS. Unlike gel electrophoresis, LC is suitable for the separation of both proteins and peptides, and can therefore be applied either upstream of 2DGE to prefractionate the sample, downstream of 2DGE to separate the peptide mixtures from single excised spots, or instead of 2DGE as the separation technology of choice. Alternative LC methods can exploit different separation principles, such as size, charge, hydrophobicity, and affinity for particular ligands. As is the case for electrophoresis, the highest resolution separations are achieved when two or more separation principles are applied one after the other in orthogonal dimensions.

In LC methods used in proteomics, the stationary phase is a porous matrix, usually in the form of packed beads that are supported on some form of column. The mobile phase, a solvent containing dissolved proteins or peptides, flows through the column under gravity or is forced through under high pressure. The rate at which any particular protein or peptide flows through the column depends on its affinity for the matrix, and matrices with different chemical and physical properties can be used to separate proteins or peptides according to different selective principles, e.g., size exclusion, ion exchange, reversed phase, or affinity chromatography.

The sequential application of different chromatographic techniques exploiting different physical or chemical separative principles can provide sufficient resolution for the analysis of very complex protein or peptide mixtures. For example, the sequential use of ion-exchange chromatography (which separates proteins by charge) and reversed-phase high performance liquid chromatography (RP-HPLC; which separates proteins approximately in a mass-dependent fashion) can achieve the same resolution as 2DGE, with added advantages of automation, increased sensitivity and better representation of membrane proteins. The compatibility of RP-HPLC with the solvents used in matrix assisted laser desorption/ionization (MALDI)-MS and ESI-MS means that HPLC is almost universally used as the final separation method in multidimensional chromatography.

Initially, multidimensional chromatography was achieved by a discontinuous process in which fractions were collected from the ion exchange or gel filtration column and then manually injected into the HPLC column. However, the need for manual sample injection can be circumvented by equipping the first column with an automatic fraction collection system and a column-switching valve. Fractions are then collected from the first column across the elution range, and the switching valve can bring the RP-HPLC column in line to receive the fractions sequentially. Alternatively, some researchers have developed apparatus comprising a single ion-exchange column coupled, via an appropriate set of switching valves, to multiple HPLC columns arranged in parallel. In this scheme, fractions emerging from the first column are directed sequentially to the multiple HPLC columns, and the cycle is repeated when the first column has been regenerated. A third strategy for multidimensional chromatography separations is the use of biphasic columns, in which the distal part of the column is filled with reversed-phase resin and the proximal part with another type of matrix (Figure 2). As long as the elution solvents for each type of resin do not interfere with

**Figure 2** Continuous multidimensional chromatography using a biphasic column. In this example, simplified from the MudPIT method, a 140 mm  $\times$  0.1 mm fused silica capillary is packed at the distal end with 5  $\mu$ m C<sub>18</sub> (reversed-phase) particles and at the proximal end with 5  $\mu$ m strong cation exchange (SCX) particles. After introduction of the sample (top arrow) fractions are eluted from the SCX resin with a stepped salt gradient. After each salt step elution, the ion-exchange fraction flows into the reversed-phase material and is eluted using a gradient of acetonitrile (bottom arrow). Reversed-phase elution and reequilibration does not affect the SCX resin. This cycle is repeated until the SCX resin is exhausted.

each other, this allows the stepped elution of fractions from the first resin and the gradient elution of second dimension fractions from the second. This technique has been developed into a system called multidimensional protein identification technology (MudPIT).

## Protein Identification

The techniques described above allow protein mixtures to be separated into their components but do not allow those components to be identified. Indeed, the individual fractions produced by such methods are usually 'anonymous'. Each spot on a 2D gel and each fraction emerging from an HPLC column look very much like any other. In the case of 2DGE, even differences in spot size and distribution provide only vague clues about protein identity. The next stage in proteomic analysis is therefore to characterize the fractions and thus determine which proteins are actually present.

Proteins can often be characterized using probes – typically antibodies – that recognize unique structural features known as epitopes. This is a very powerful way to isolate and identify individual proteins but it is difficult to apply on a proteomic scale (see the section 'Protein chip technology' below). The gold standard method for identifying a protein is sequencing by Edman degradation, which involves the step-wise chemical removal of single amino acid residues, allowing short sequences to be determined that can be used to search sequence databases. While Edman degradation remains the most useful technique for N-terminal sequencing, it is slow and laborious, and many proteins are blocked to this technique because the N-terminal amino acid is chemically modified.

In the early 1990s, the identification of proteins was revolutionized by simultaneous development in two areas. First, in MS, techniques became available for the soft ionization of macromolecules, preventing the ions from fragmenting indiscriminately. The two techniques used most widely for ionization in proteomics today are:

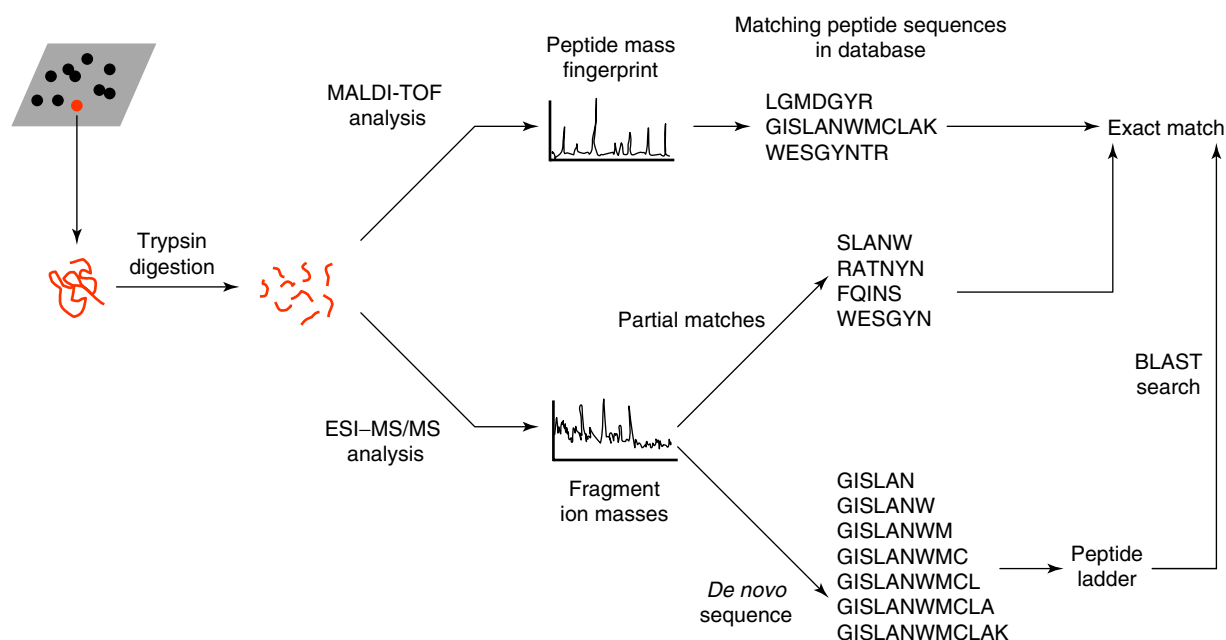

- **MALDI.** The analyte is mixed with a large excess of an aromatic matrix compound that can absorb energy from the laser used with the mass spectrometer. For example, the matrix compound  $\alpha$ -cyano-4-hydroxycinnamic acid can absorb the energy from a nitrogen UV laser (337 nm). The analyte and matrix are dissolved in an organic solvent and placed on a holder that can handle multiple samples. The solvent evaporates leaving matrix crystals in which the analyte is embedded. The holder is placed in the vacuum chamber of the mass spectrometer and a high voltage is applied. At the same time, the crystals are targeted with a short laser pulse. The laser energy is absorbed by the crystals and emitted (desorbed) as heat, resulting in rapid sublimation that converts the analyte into gas-phase ions. These accelerate away from the probe through the analyzer toward the detector. MALDI is used predominantly for the analysis of simple peptide mixtures, such as the peptides derived from a single spot from a 2D gel.
- **Electrospray ionization (ESI).** The analyte is dissolved and forced through a narrow needle held at a high voltage. A fine spray of charged droplets emerges from the needle and is directed into the vacuum chamber of the mass spectrometer through a small orifice. As they enter the mass spectrometer, the droplets are dried using a stream of inert gas, resulting in gas-phase ions that are accelerated through the analyzer toward the detector. Because ESI produces gas-phase ions from solution, it is readily integrated with upstream protein separation by liquid-phase methods, particularly capillary electrophoresis and

LC. Whereas MALDI-MS is used to analyze simple peptide mixtures, LC – ESI-MS is more suited to the analysis of complex samples.

These ionization techniques can be combined with a variety of instruments for the sensitive determination of peptide masses. Widely used instruments include triple quadrupole, time-of-flight (TOF), hybrid quadrupole-TOF, TOF-TOF, quadrupole-ion trap, and FT-ICR mass spectrometry.

The second development was the development of algorithms that could be used to search sequence databases with MS data. There are two general approaches, which are compared in Figure 3:

- The analysis of intact peptide ions. This allows the masses of intact peptides to be calculated, and these masses can be used to identify proteins in a sample by correlative database searching.
  - The analysis of fragmented ions. Intact peptide ions are fragmented randomly, generally by collision with a stream of inert gas (collision induced dissociation, CID). This allows the masses of peptide fragments to be determined, and the resulting CID spectrum can be used either for correlative database searching or to derive *de novo* sequences. In the latter case, the derived sequences can be used as standard queries in similarity search algorithms derived from BLAST and FASTA.
- The sample of interest should comprise a single protein or a simple mixture, e.g., an individual spot from a 2D gel or a single LC fraction. The sample is digested with a specific cleavage reagent, usually trypsin.
  - The masses of the peptides are determined, e.g., by MALDI-TOF-MS.
  - The experimenter chooses one or more protein sequence databases to be used for correlative searching.
  - The algorithm carries out a virtual digest of each protein in the sequence database using the same cleavage-specificity as trypsin (or whichever other reagent has been used experimentally) and then calculates theoretical peptide masses for each protein.
  - The algorithm attempts to correlate the theoretical peptide masses with the experimentally determined ones.
  - Proteins in the database are ranked in order of best correlation, usually with a significance threshold based on a minimum number of peptides matched.

**Figure 3** Protein identification by mass spectrometry. In a typical strategy, digested peptides are analyzed by MALDI-TOF-MS in order to determine the masses of intact peptides. These masses can be used in correlative database searches to identify exact matches. If this approach fails, ESI-MS/MS analysis can be used to generate peptide fragment ions. These can be used to search less robust data sources and to produce *de novo* peptide sequences. (Reproduced with permission from Twyman RM (2004) *Principles of Proteomics*. Abington, UK: Bios/Garland Publishers.)

There are several reasons why PMF may not work, including the absence of the sequence from the database, insufficient instrument sensitivity, nonspecific cleavage of the protein, the existence of several polymorphic variants of the protein with different masses, the presence of unanticipated post-translational modifications (either natural or artifactual) or the presence of contaminants. Where PMF fails to identify any proteins matching those present in a given sample, the CID spectrum of one or more individual peptides may provide important additional information. The data can be used in two ways. First, the 'uninterpreted' fragment ion masses can be used in correlative database searching to identify proteins whose peptides would likely yield similar CID spectra under the same fragmentation conditions. In probability based matching, virtual CID spectra are derived from the peptides of all protein sequences in the database and these are compared with the observed data to derive a list of potential matches. In cross-correlation, it is the degree of overlap between the observed and predicted peaks that determines the best potential match. Second, the peaks of the mass spectrum can be 'interpreted', either manually or automatically, to derive partial *de novo* peptide sequences that can be used as standard database search queries. The advantage of both these approaches is that correlative searching is not limited to databases of full protein sequences.

The interpretation of CID data is complex because fragmentation produces a diverse collection of thousands of different ions. The most informative fragments are those in which breakage has occurred along the polypeptide backbone, because these represent strings of contiguous and intact amino acids. If the charge remains on the N-terminal fragment, it is known as a b-series ion whereas if it remains on the C-terminal fragment, it is known as a y-series ion. Interpretation generally involves the arrangement of b- or y-series ions in order of increasing mass. The differences in mass between consecutive ions in either series should correspond to the masses of individual amino acids, and this can be used to derive a short sequence or peptide tag.

## Quantitative Proteomics and the Analysis of Post-Translational Variants

The objective in many proteomic experiments is to identify proteins whose abundance differs across two or more related samples. This may include variations in absolute protein levels or variations in the stoichiometry of different forms of modification, such as phosphorylation. At the current time, protein quantitation in proteomics relies primarily on the use of

general labeling or staining, or on the selective labeling or staining of particular classes of proteins. The chosen strategy depends largely on how the protein samples are prepared and fractionated, and can be divided into two broad categories: those based on the image analysis of 2D gels, and those based on differential labeling of samples for separation by LC followed by MS.

A range of stains and labels is available for use on 2D-gels and these differ in their sensitivity, specificity, and compatibility with MS. The most sensitive methods are silver staining, radioactive labeling, and fluorophore labeling, particularly the SYPRO reagents available from Molecular Probes Inc. (recently acquired by Invitrogen) which also have a broad linear dynamic range. Depending on the choice of label, the gel image is captured using a scanning device – a phosphorimager, a charge coupled device (CCD) camera, a densitometer or a fluorescence reader. Each spot is then converted into quantitative digital data, which requires sophisticated visual analysis software. Further software is required to recognize and compare corresponding spots on separate gels representing related samples (e.g., disease and healthy tissue), providing a spot-by-spot comparison across multiple gels. This approach is sometimes problematical because of the difficulties in reproducing running conditions accurately, and recently a number of multiplexed techniques have become available where several, differentially labeled samples can be run concurrently. Such techniques include difference gel electrophoresis, where individual samples are labeled with different fluorophores prior to electrophoresis, and the use of different stains to label different populations of proteins. The latter has been most useful for studying proteins with particular forms of post-translational modification (e.g., Pro-Q Diamond which selectively stains phosphoproteins, fluorescent labeled anti-phosphotyrosine antibodies, and Pro-Q Emerald which selectively stains glycoproteins) and proteins with different functional properties (e.g., the ability to bind certain drugs or substrates).

Protein quantitation by MS makes it possible to use in-line liquid-phase separation methods such as multidimensional chromatography and capillary electrophoresis. Quantitation can be carried out by comparing peptide ion currents but this is inherently inaccurate and is biased by instrument design. Instead, quantitation is often based on the use of stable isotopes. The general approach is to label alternative samples with equivalent reagents, one of which contains a heavy isotope and one of which contains a light isotope. The samples are mixed, separated into fractions, and analyzed by MS. The ratio of the two isotopic variants can be determined from the heights

of the peaks in the mass spectra and used to identify proteins with differential abundance.

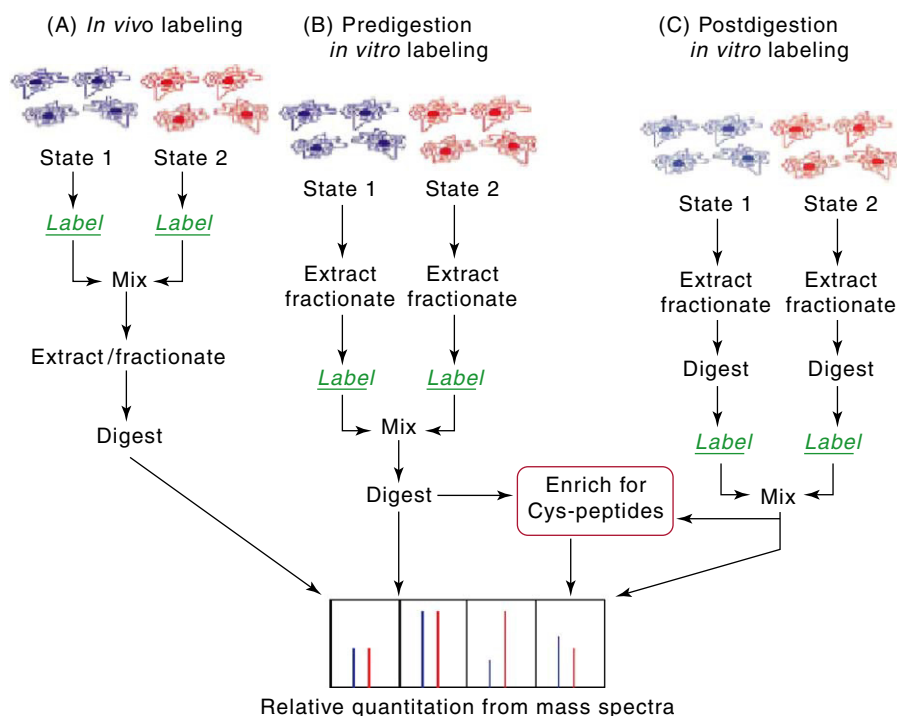

There are several different approaches to quantitative MS, including metabolic labeling *in vivo* (useful for cell assays), nonselective labeling of peptides with heavy oxygen during trypsin cleavage, and the use of isotope-coded affinity tags (Figure 4). These are biotinylated derivatives of iodoacetamide, a reagent that reacts with the cysteine side chains of denatured proteins. Two versions of the reagent are used, one normal or light form and one heavy or deuterated form in which a hydrogen atom is replaced by deuterium. The heavy and light forms are used to label different protein samples and then the proteins are combined and digested with trypsin. The biotin allows cysteine-containing peptides to be isolated from the complex peptide mixture through affinity to streptavidin, therefore considerably simplifying the number of different peptides entering the mass spectrometer.

Methods similar to ICAT can also be used for the LC-MS analysis of phosphoproteins and other variants. In this case, a reagent is chosen that selectively modifies the phosphate group. For example, ethanedithiol can be used to replace the phosphate group of phosphoserine and phosphothreonine residues by  $\beta$ -elimination under strongly alkaline conditions, leaving a thiol group that can be used to attach an isotope-coded biotin affinity tag. Phosphopeptides

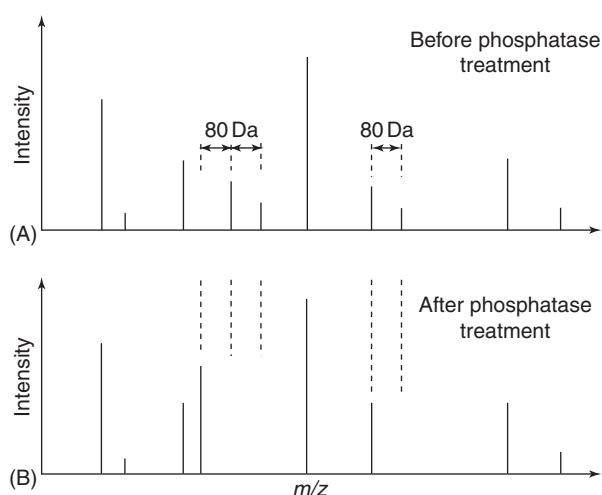

can be detected directly in tandem mass spectrometers using particular running modes. Standard MALDI-TOF analysis can identify ions with masses shifted by 79.983 compared to predicted masses, representing the additional phosphate group. Parallel analysis in which the sample has been treated with alkaline phosphatase, which removes phosphates, can also be helpful, since peaks corresponding to phosphopeptides in the untreated sample should be absent from the treated sample (Figure 5). In precursor ion scan mode, the first analyzer scans the ion stream and directs selected ions into the collision cell, while the second analyzer looks for diagnostic reporter ions, such as  $\text{H}_2\text{PO}_4^-$ ,  $\text{PO}_3^-$ , and  $\text{PO}_2^-$ , which have masses of  $\sim 97$ ,  $79$ , and  $63$ , respectively. In neutral loss scan mode, both analyzers are set to scan the ion stream. The first scans the full mass range, and the second scans a parallel range but at an  $m/z$  ratio that is  $98/z$  lower, with the intention of detecting the neutral loss of  $\text{H}_3\text{PO}_4$ .

## Other Proteomics Technologies

While 2DGE/LC and MS represent the major technologies for proteome analysis, proteomics is not limited to the analysis of protein abundance and expression. In the limited space available, a summary is provided of the other major technology platforms,

**Figure 4** Overview of MS-based strategies for quantitative proteomics. Depending on the point at which the label is introduced, most procedures are classified as: (A) *in vivo* labeling, (B) predigestion labeling *in vitro*, or (C) postdigestion labeling *in vitro*.

**Figure 5** Phosphopeptide identification by MALDI-TOF-MS mapping combined with alkaline phosphatase treatment. (A) The MALDI-TOF-MS spectrum of a proteolytic digest. Phosphopeptides are indicated by peaks shifted by multiples of 80 Da ( $\text{HPO}_3^- = 80 \text{ Da}$ ) relative to predicted unphosphorylated peptide masses. (B) The disappearance of such peaks upon treatment with a phosphatase confirms their identity as phosphopeptides.

which allow the investigation of protein sequences, structures, interactions, and biochemical functions.

### Sequence and Structural Proteomics

Although proteomics as we understand it today would not have been possible without advances in DNA sequencing, protein sequencing by Edman degradation for many years provided a crucial link between the activity of a protein and the genetic basis of a particular phenotype. It was not until the mid-1980s that it first became commonplace to predict protein sequences from genes rather than to use protein sequences for gene isolation.

The increasing numbers of stored protein and nucleic acid sequences, and the recognition that functionally related proteins often had similar sequences, catalyzed the development of statistical techniques for sequence comparison which underlie many of the core bioinformatic methods used in proteomics today. Nucleic acid sequences are stored in three primary sequence databases – GenBank, the EMBL nucleotide sequence database, and the DNA database of Japan (DDBJ) – which exchange data every day. These databases also contain protein sequences that have been translated from DNA sequences. A dedicated protein sequence database, SWISS-PROT, was founded in 1986 and contains highly curated data concerning over 70 000 proteins. A related database, TrEMBL, contains automatic translations of the nucleotide sequences in the EMBL database and is not manually curated.

Since similar sequences give rise to similar structures, it is clear that protein sequence, structure, and function are often intimately linked. The study of three-dimensional protein structure is underpinned by technologies such as X-ray crystallography and nuclear magnetic resonance spectroscopy, and has given rise to another branch of bioinformatics concerned with the storage, presentation, comparison, and prediction of structures. The Protein Data Bank was the first protein structure database and now contains more than 10 000 structures. Technological developments in structural proteomics have centered on increasing the throughput of structural determination and the initiation of systematic projects for proteome-wide structural analysis. A selection of proteomics databases is listed in Table 2.

### Interaction Proteomics

This branch of proteomics considers the genetic and physical interactions among proteins as well as interactions between proteins and nucleic acids or small molecules. The analysis of protein interactions can provide information not only about the function of individual proteins but also about how proteins function in pathways, networks, and complexes. It is a field that relies on many different technology platforms to provide diverse information, and is closely linked with functional proteomics and the large-scale analysis of protein localization. Conceptually the most ambitious aspect of interaction proteomics is the creation of proteome linkage maps based on binary interactions between individual proteins and higher order interactions determined by the systematic analysis of protein complexes. Key technologies in this area include the yeast two-hybrid system (a genetic assay for binary interactions) and MS for the analysis of protein complexes. Interactions between proteins and nucleic acids underlie many important processes including gene regulation, while protein interactions with small molecules are also of interest, e.g., enzymes interacting with their substrates and receptors with their ligands. These types of interactions are often investigated using biochemical assays and structural analysis methods such as X-ray crystallography. The characterization of protein interactions with small molecules can play an important role in the drug development process.

### Functional Proteomics

The most straightforward way to establish the function of a protein is to test that function directly. Functional proteomics is a relatively new development in which protein functions are tested directly but on a large scale. An example is the systematic

testing of expressed proteins for different enzymatic activities, as described in a landmark publication by Martzen and colleagues (see 'Further reading' section).

### Protein Chip Technology

Protein chips are miniature devices on which proteins, or reagents that capture proteins from solution, are applied in an array. There are many different types of protein chip, some used to analyze protein abundance and others used to study protein functions.

This emerging technology has the potential to considerably improve the throughput of protein analysis, particularly with the recent advent of a whole proteome chip for the yeast *Saccharomyces cerevisiae*. The various different types of protein chip that have been described are summarized below:

- Antibody chips. These consist of arrayed antibodies and are used to detect and quantify specific proteins in a complex mixture. They can be thought of as miniaturized high-throughput immunoassay devices.

- **Antigen chips.** The converse of antibody chips, these devices contain arrayed protein antigens and are used to detect and quantify antibodies in a complex mixture.
- **Universal protein chips (functional arrays).** These devices may contain any kind of protein arrayed on the surface and can be used to detect and characterize specific protein–protein and protein–ligand interactions. Various detection methods may be used, including labeling the proteins in solution or detecting changes in the surface properties of the chip, e.g., by surface plasmon resonance. Included within this category are lectin arrays, which are used to detect and characterize glycoproteins.
- **Protein capture chips.** These devices do not contain arrayed proteins, but other molecules that interact with proteins as broad or specific capture agents. Examples include oligonucleotide aptamers and chips containing molecular imprinted polymers as specific capture agents, or the proprietary protein chips produced by companies such as BIAcore Inc. and CIPHERGEN Biosystems Inc., which employ broad capture agents based on differing surface chemistries to simplify complex protein mixtures.
- **Solution arrays.** The latest generation of protein chips is being released from the 2D array format to increase their flexibility and handling capacity. Such devices may, for example, be based on coded microspheres or barcoded gold nanoparticles.

## Introduction

Purines, pyrimidines, nucleosides, and nucleotides belong to a biologically important class of compounds in which several of these derivatives constitute nucleic acid components (typical structures of these compounds are given in **Figure 1**). Purines and pyrimidines are azaheterocyclic bases. Purines are constituted of two nitrogen-containing rings (**Figure 1**, structures (1)–(3)), whereas pyrimidines contain only one nitrogen-containing ring (**Figure 1**, structures (4)–(6)). When a purine or a pyrimidine is attached to the C-1 position of a sugar, the corresponding structure is called a nucleoside (**Figure 1**, structures (7) and (8)), whereas a heterocyclic base-sugar-phosphoric acid unit is called a nucleotide (**Figure 1**, structures (9) and (10)). A dinucleotide consists of two nucleotide units connected by phosphate groups (**Figure 1**, structure (11)). These compounds are of major biological and biochemical interest since the backbone of nucleic acid molecules (DNA, RNA) is a polynucleotide chain, made up of a large number of various nucleotide units joined by phosphate groups.

The names of nucleosides are derived from the names of the corresponding heterocyclic bases combined with the name of the sugar (ribose or deoxyribose). In some cases, special names are used: for example, cytidine is cytosine- $\beta$ -D-ribose.

Nucleotides, which contain one, two, or three phosphate groups, are named as mono-, di-, or triphosphate derivatives of the nucleosides: for example, cytidine 5'-monophosphate (CMP), 5'-diphosphate, and 5'-triphosphate are the nucleotides derived from cytidine.

Many purine and pyrimidine derivatives, including mercapto-, fluoro-, and azasubstituents, are contained in pharmaceuticals, and therefore their metabolism has to be monitored in living organisms. For these reasons, their determination has been the object of much attention during the last 25 years, and a number of methods have been proposed. These procedures have been applied widely to the determination of purines, pyrimidines, and their derivatives in plant and animal tissues as well as in various biological fluids such as blood plasma, whole blood,

and urine. This article briefly reviews the various analytical methods used for determining purines, pyrimidines, and their derivatives, as well as the special methods for nucleotides. Performances and analytical figures of merit are compared. Practical applications for the determination of these compounds in biological fluids and tissues are also discussed.

## Chromatographic Methods

Because biological samples contain generally a relatively large number of purines, pyrimidines, nucleotides, and/or nucleosides, it is necessary to use separation methods to simultaneously analyze multi-component mixtures of these derivatives. Several chromatographic methods have been reported such as paper chromatography (PC), thin-layer chromatography (TLC), gas chromatography, and liquid chromatography (LC). The performances of PC, TLC, and LC are described in detail below.

### Paper Chromatography

Although paper chromatography is often considered outmoded, it remains one of the most widely used techniques in analyzing mixtures of purine and pyrimidine derivatives, including nucleosides and nucleotides. These compounds generally absorb ultraviolet (UV) radiation in the 250–300 nm range. Therefore, they can be easily detected on chromatograms by irradiation with a UV lamp emitting in this wavelength region. Under these conditions, dark, UV-absorbing spots are observed against the natural fluorescence of the chromatogram paper, indicating the location of the derivatives. When elution is performed carefully, PC makes it possible to achieve quantitative recovery of purine and pyrimidine derivatives from chromatograms.

Several solvent systems have been proposed for PC such as butan-1-ol/acetic acid/water, butan-1-ol/ammonia/water, butanol-1-ol/water, ethanol/ammonium acetate, and methanol/formic acid/water. Generally, the separation of a complex mixture of bases, nucleosides, and nucleotides requires using successively two solvent systems for two-dimensional PC. Since  $R_F$  values may vary slightly with chromatographic conditions, it is recommended that identifications be checked by comparing the  $R_F$  values of the mixture components with those of authentic samples in several solvent systems.

**Figure 1** Examples of structures of purines: (1) adenine; (2) hypoxanthine; (3) guanine (G). Pyrimidines: (4) uracil; (5) cytosine (C); (6) thymine (T). Nucleosides: (7) adenosine (A); (8) uridine (U). Nucleotides: (9) 3',5'-cAMP; (10) adenosine 5'-triphosphate. Dinucleotide: (11) NAD<sup>+</sup>.

### Thin-Layer Chromatography

Because of its great versatility and simplicity, TLC constitutes an important analytical tool for the

separation and determination of purine and pyrimidine derivatives. The bases and nucleosides and nucleotides can be separated on thin layers of silica gel G, unmodified cellulose, chemically modified

cellulose, and aluminum oxide. The choice of solvent mixture depends on the specific compounds under study and on the type of thin layers used. Typically, 2-methylbutan-2-ol/formic acid/water (3:2:1, v/v) gives a good overall separation of nucleotides, while butan-1-ol/acetone/acetic acid/ammonia (5% v/v)/water (45:15:10:10:20) separates nucleoside mono-, di-, and triphosphates on unmodified cellulose. A high acetonitrile content seems to increase the rapidity of elution of nucleosides and nucleotides, as compared with alcohol-containing mixtures, when silica gel and microcrystalline cellulose are utilized.

Compounds separated by TLC on cellulose or silica gel can be detected by visualizing the spots in UV radiation from a suitable wavelength-emitting source (200–250 nm). An alternative, and generally more sensitive, detection method can be used on silica gel by spraying the developed chromatogram with a solution of a fluorescent compound, such as 2',7'-dichlorofluorescein (0.01% w/v in ethanol with a few drops of ammonia) or uranyl acetate (1% w/v in water). Limits of detection using TLC for purines range between ~0.1 µg per spot (UV detection) and 10 ng per spot (fluorescence detection).

### Liquid Chromatography

Liquid chromatography is a rapid, selective and sensitive technique which can be adapted to the analysis of extracts from a variety of biological sources. It constitutes an excellent method for the analysis of nucleotides, nucleosides, purines, and pyrimidines bases.

**Analysis of nucleotide mixtures in tissues** Nucleotide mixtures are found in human, animal, and plant tissues, and it is essential to select convenient extraction procedures in order to minimize chromatographic artifact formation. Also, preliminary purification is needed to remove interfering natural substances that can bind irreversibly to the chromatographic column packing, producing loss of resolution.

The extraction methods for free nucleotides from human, animal, and plant tissues are generally based on the use of cold acid extractants, which also have the role of suppressing enzymatic activity and precipitating proteins. Usually, biological samples are disrupted in the presence of an extractant, and the extracts are centrifuged or filtered. Dilute solutions of perchloric acid or trichloroacetic acid (TCA) are utilized as extractants in most cases. However, caution is recommended in the use of TCA preceding LC because it can produce chromatographic artifacts affecting the quantification of nucleotides. Formic

acid-based solutions have also been proposed for the extraction of nucleotides from microorganisms and plant tissues.

The purification procedure consists of several steps. First, the perchloric acid extract is centrifuged (2000–16 000 g, for 5–10 min), and the supernatant is neutralized with potassium hydroxide solution. Then the pH of the aqueous solution containing the nucleotides is adjusted to an appropriate value (between 5.0 and 7.0), and the precipitated potassium perchlorate, which has a low solubility in cold water, is removed by centrifugation. In the majority of human and animal tissues, and of microbial cells, it is convenient to chromatograph this extract. In some cases, however, especially where a large number of constituents have to be resolved in a single chromatographic step, it may be necessary to further purify the extract by a chemical reaction or by a preliminary chromatographic separation.

Liquid chromatographic analysis of nucleotide mixtures is based on several separation techniques such as ion exchange, reversed-phase, and reversed-phase ion-pair chromatography. The use of microparticulate, chemically bonded anion exchange allows the separation, on a single column, of a mixture of all the commonly occurring nucleotides, with a linear gradient elution system, as shown in **Figure 2**. Isocratic reversed-phase LC systems have also been proposed for the separation of a relatively large number of nucleotides, including ribonucleotides, deoxynucleotides, cyclic nucleotides, and deoxycyclic nucleotides with good speed and resolution.

**Determination of purines, pyrimidines, and nucleosides** Although several LC procedures are available for separating mixtures of purines, pyrimidines, and nucleosides, it is generally more convenient to use specific columns for differentiating between these different classes of compounds.

Liquid chromatographic analysis of free purine and pyrimidine bases can be carried out on either cation-exchange or reversed-phase columns. The separation of a mixture of 10 methylated xanthines has been accomplished using reversed-phase LC on a column of Apex Octadecyl 3 µm kept at 50°C, in less than 2 min. This mixture included caffeine, theophylline, and theobromine, which are very important compounds in the food and pharmaceutical industries.

The separation of nucleoside mixtures generally requires a reversed-phase system with a stepwise gradient elution, using phosphate buffers and increasing concentrations of methanol. Under these conditions, 20 nucleosides can be separated in less than 24 min (**Figure 3**).

**Figure 2** Reversed-phase LC separation on  $\mu$  Bondapak C<sub>18</sub> of a reference mixture of commonly occurring free-nucleotides. A linear gradient (30 min) was used with  $0.2 \text{ mol l}^{-1} \text{ KH}_2\text{PO}_4$  (pH 4.0) as the initial eluant, and  $0.2 \text{ mol l}^{-1} \text{ KH}_2\text{PO}_4$  containing 20% (v/v) methanol, also at pH 4. Flow rate  $2 \text{ ml min}^{-1}$ . The positions of 2'-deoxyadenosine 5'-triphosphate (dATP) and 2'-deoxythymidine-5'-triphosphate (dTTP), determined from other separations on the same column, are indicated by arrows (Reprinted with permission from Brown EG, Newton RP, and Shaw NM (1982) Analysis of the free nucleotide pools of mammalian tissues by high-pressure liquid chromatography. *Analytical Biochemistry* 123: 378–388; © Elsevier.)

Ultraviolet spectrophotometric, spectrofluorimetric, and electrochemical detectors are utilized for most compounds. Purines such as hypoxanthine and xanthine can be determined fluorimetrically by means of a reaction using xanthine oxidase and producing hydrogen peroxide. Generally, the LC

detection limits for purines, pyrimidines, and nucleosides are rather low, in the nanogram range.

## Electrophoresis

Electrophoresis has emerged recently as a promising method for the determination of purines, pyrimidines, nucleosides, and nucleotides. Two techniques are used: high-voltage paper electrophoresis (PE) and capillary electrophoresis (CE).

### High-Voltage Paper Electrophoresis

High-voltage PE is a separation technique based on the differences in the electrophoretic mobilities of charged compounds. Commercially available apparatus consist of a high-voltage (1–10 kV) supply that is connected across the opposite ends of an electrophoresis paper. Application of a convenient electric potential induces a current to flow along the sheet of paper, producing a migration of ions. Under certain conditions of pH and current, the extent of migration of the components of a mixture is related to the charges located on the individual chemical species. Therefore, the number of ionizable groups and their  $pK_a$  values are critical for determining the electrophoretic behavior. In the case of purines, pyrimidines, and nucleosides, the  $pK_a$  values of groups such as amino and keto groups are important for electrophoretic separation. Nucleotides can be separated from the other compounds on the basis of the  $pK_a$  values of their phosphoric acid groups. As would be expected from their difference in negative charge, nucleoside mono-, di-, and triphosphates migrate at different speeds toward the anode, and they can be separated easily one from another.

Volatile 'buffers' with a pH ranging from 2.0 to 9.0 are generally utilized in PE. Typically, a formic acid/acetic acid/water mixture at pH 2.0 is used for nucleotides. Noncyclic 5'-nucleotides can be separated from cyclic 3',5'- nucleotides, which are simultaneously present in animal, plant, and microbial tissues, by applying a nonvolatile sodium borate buffer at pH 9.3; indeed borate interacts specifically with the *cis-vicinal* hydroxyl groups of 5'-nucleotide ribose but not with cyclic nucleotides.

### Capillary Electrophoresis

In recent years, CE has developed into a very sensitive and selective analytical technique for the determination of purines, pyrimidines and their metabolites, and nucleotides. It allows charged compounds to be separated in a capillary filled with the electrophoresis buffer through application of a high voltage (typically, 10–30 kV) over the length of the fused silica capillary tube. The electrophoretic migration rate of charged compounds, which move toward the electrode with opposite charge, depends on the charge and the size of the molecules and is proportional to the electrical field strength. Generally, the efficiencies obtained in CE are much greater than those in other separation methods. However, a drawback of CE is that the mass flow is limited owing to the small dimensions of the capillary used, resulting in flow rates of only 5–15  $\mu\text{L min}^{-1}$ .

The separation of mixtures of purines, pyrimidines or nucleotides can take place in 15–25 min, depending on the molecular structure, charge, and experimental conditions. In **Figure 4**, an electropherogram is presented, showing that the separation of a mixture of eight nucleotide monophosphates (prepared from LC-purified samples) is complete in approximately 16 min. The method involves micellar electrokinetic capillary chromatography (MECC), in which a surfactant at concentrations greater than the critical micellar concentration is added to the buffer solutions.

Several detection systems are utilized in CE for the analysis of nucleoside and nucleotide mixtures. The performances of UV-visible absorption, conductance, electrochemical,  $\alpha$ - $^{32}\text{P}$  radiochemical and fluorescence detectors and mass spectral interfacing have been compared recently. Although UV-visible absorption is generally considered as not very sensitive, low limits of detection (LODs) of  $8 \times 10^{-8} \text{ mol L}^{-1}$  have been reported for purine metabolites using this method. The conductivity technique suffers from poor sensitivity. Electrochemical detection has a higher sensitivity, but its usefulness is limited by the fact that only electroactive species can be detected. Detection by mass spectrometry (MS) leads to poor sensitivity and implies expensive instrumentation. Radiochemical detection has been applied to  $\alpha$ - $^{32}\text{P}$ -labeled thymidine, cytidine, and adenosine

**Figure 4** MECC-laser induced fluorescence analysis of deprotonated dansyl hydroxide (A), dansyl-dTMP (B), dansyl-dCMP (C), dansyl-5 methyl dCMP (D), dansyl-dAMP (E), dansyl-dGMP (F), dansyl-8-OH dGMP (G), and dansyl 8-(*N*-2-acetylaminofluorene) dGMP (H). **Table 1** Comparison of state-of-the-art LODs<sup>a</sup> with LC and CE in the analysis of various nucleosides and nucleotides

Detection system	LC		CE	
	Amount (mol)	Concentration (mol l <sup>-1</sup> )	Amount (mol)	Concentration (mol l <sup>-1</sup> )
Absorption	$2 \times 10^{-9b}$	$2 \times 10^{-4b}$	$7 \times 10^{-14b}$	$3 \times 10^{-5b}$
Electrochemical	$2 \times 10^{-13c}$	$2 \times 10^{-8c}$	—	—
Fluorescence	$2 \times 10^{-13d}$	$2 \times 10^{-8d}$	$6 \times 10^{-18d}$	$1 \times 10^{-9d}$
Radiochemical	—	—	$72 \times 10^{-18e}$	$1 \times 10^{-10e}$

<sup>a</sup>The LOD is defined as the amount (mol) or concentration (mol l<sup>-1</sup>) of analyte giving a signal-to-noise ratio of 3.

<sup>b</sup>For dansyl-2'-deoxyadenosine-5'-monophosphate (dAMP), dansyl-2'-deoxycytidine-5'-monophosphate (dCMP), dansyl-2'-deoxyguanine-5'-monophosphate (dGMP), and dansyl-2'-deoxythymidine-5'-monophosphate (dTMP).

<sup>c</sup>For 8-hydroxy-2-deoxyguanine.

<sup>d</sup>For dAMP, dCMP, dGMP, dTMP, and corresponding nucleosides-5',-mono-, di- and triphosphates.

<sup>e</sup>For adenosine-5'-triphosphate, cytidine-5'-triphosphate, and thymidine-5'-triphosphate.

(Reprinted with permission from Lee T, Yeung ES, and Sharma M (1991) Micellar electrokinetic capillary chromatographic separation and laser-induced fluorescence detection of 2'-deoxynucleoside-5'-monophosphates of normal and modified bases. *Journal of Chromatography and Biomedical Applications* 565: 197–206; © Elsevier.)

triphosphates, resulting in very low LODs of  $\sim 1 \times 10^{-10}$  mol l<sup>-1</sup>. Laser-induced fluorescence is also a very sensitive technique, with LODs in the  $10^{-9}$  mol l<sup>-1</sup> range for nucleoside monophosphates. Table 1 shows state-of-the-art LODs for several detection systems coupled to CE or LC in the analysis of derivatized or native nucleosides. It can be seen that the absolute LODs (expressed in moles) for CE are generally five orders of magnitude lower than those for LC, using the same detection system. In contrast, the concentration LODs (in mol l<sup>-1</sup>) have only a difference of one order of magnitude. This is mainly due to the smaller sample volumes used in CE as compared with LC.

## Spectrometric Methods

Spectrometric methods are extremely useful for structural investigation and identification of purines, pyrimidines, nucleosides, and nucleotides. They allow the provisional identification of these compounds, made on the basis of chromatographic and electrophoretic behavior, to be confirmed. The application of MS, UV absorption spectrophotometry, and phosphorescence spectrometry to the identification and determination of purines, pyrimidines, and their derivatives is reviewed in the following sections.

### Mass Spectrometry (MS)

Although the development of conventional mass spectrometric techniques has been relatively slow in the area of purines and pyrimidines, primarily because of the low volatility of these compounds and hence the difficulty of achieving ionization, recent advances such as fast atom bombardment (FAB) and collision-induced dissociation (CID) have opened up this field.

FAB is a method of relatively soft ionization that has been applied to many volatile and thermally labile, biologically important compounds over a large mass range. Although FAB–MS provides information on the molecular mass of cyclic nucleotides, it does not allow detailed structural identification. For instance, isomers often provide similar spectra. For example, the FAB mass spectra of the two isomers 3',5'- and 2',3'-cyclic adenosine monophosphate are practically identical. The employment of CID of ions results in mass-analyzed kinetic energy spectra (MIKES), which provide the means of differentiating these cyclic nucleotide isomers.

Therefore the use of FAB–MS combined with CID–MIKES can be applied to the qualitative analysis of cyclic nucleotides in mammalian and higher plant tissue extracts and to the identification of synthetic cyclic nucleotide derivatives. It provides unambiguous evidence of the identity of nucleotides, in contrast with chromatographic, enzymatic, and radioimmunoassay methods, which often lead to equivocal results.

Quantitative analysis of cyclic nucleotides in protein kinase activity can also be performed using the FAB–MIKES technique. It gives results comparable with those obtained by conventional radiometric assay for monitoring the kinetics of cyclic nucleotide phosphodiesterase activity.

The potential of laser microprobe mass spectrometry (LMMS) has been investigated for structural characterization of nucleosides and nucleotides. This technique is based on the measurement of ions formed promptly by direct desorption and ionization (DI) of solid microscopic samples. The DI process is very fast for nucleosides, which makes it possible to apply a relatively high laser energy to the sample. In the case of nucleosides, LMMS gives

satisfactory results based on the mass spectral peaks of positive and negative ions. The molecular mass of these compounds can easily be determined from the relatively intense signal. In contrast, LMMS analysis of nucleotides is more difficult. The sensitivity is lower, and the DI process is slower compared with nucleosides. More work is needed for optimizing the experimental conditions of analysis of nucleotide sodium salts.

### UV Absorption Spectrophotometry

Ultraviolet absorption spectrophotometry constitutes a very rapid and simple method for the identification and determination of purines, pyrimidines, and their derivatives. Because many of these compounds can undergo keto–enol tautomerism – a pH-dependent phenomenon – and/or prototropic equilibria, caution should be exercised in selecting the pH of the aqueous solution used for spectrophotometric measurements. As a consequence, spectra obtained at arbitrary pH values may correspond to the summation of spectra belonging to various species. Knowledge of the  $pK_a$  values of purines and pyrimidines is necessary to choose convenient pH values for spectral measurements.

Generally, UV absorption spectra can be utilized to determine the family to which an unknown base, nucleoside, or nucleotide belongs. Indeed, the chromophore of the nucleosides or nucleotides is typical of the purine or pyrimidine structure, with different maximum absorption wavelengths in the adenosine, guanosine, cytosine, or thymidine series. For example, it is possible to differentiate readily the UV absorption spectra of guanosine (G), G-monophosphate (GMP), deoxy GMP (dGMP), G-diphosphate (GDP), and G-triphosphate (GTP), from those of adenosine (A), AMP, dAMP, ADP, and ATP.

For mixtures of several nucleotides and/or nucleosides, however, spectroscopic analyses become difficult because UV spectra contain only a small number of absorption bands and have a very similar shape. In these cases, it is necessary to evaluate precisely and in detail the minor differences in the spectra, such as the position of the shoulders and the relative intensities of the various bands, which are often sufficient for multicomponent analysis. Two approaches, the so-called principal component regression (PCR) and partial least-squares (PLS) regression analyses, with Fourier preprocessing of UV spectra, have been developed. These methods can monitor continuously entire spectral regions, and they are generally reliable and accurate. They have allowed the composition of 14 unknown mixtures of dAMP, dCMP, dGMP, and dTMP to be analyzed, with average percent errors of 0.60–1.85%. The presence of a protein

(up to 36% of albumin added to the mixtures) is found not to interfere significantly with the spectral results of the PCR and PLS approaches.

The analysis of mixtures of purines and pyrimidines can also be carried out by using first- and second-derivative UV spectra. Indeed, these derivative spectra contain many more features, such as peaks, shoulders, and/or trough wavelengths, useful for identification purposes, than the zero-order spectra. An example is provided in Figure 5, which shows zero-order first-, and second-derivative spectra of a caffeine-6-methylpurine (1:1) mixture. Second-derivative spectra can be utilized for the identification of binary mixtures of purines and pyrimidines, as well as for their determination. Moreover, several computer programs have been described for resolving

**Figure 5** Zero-order (1), first-derivative (2), and second-derivative (3) UV spectra of a mixture of caffeine (CAF) ( $5 \times 10^{-5} \text{ mol l}^{-1}$ ) and 6-methyl purine (MP) ( $5 \times 10^{-5} \text{ mol l}^{-1}$ ). (Reprinted with permission from Aaron JJ and Gaye MD (1988) Analysis of mixtures of purines and pyrimidines by first and second derivative ultraviolet spectrometry. *Talanta* 35: 513–518; © Elsevier.)

second-derivative UV spectra and elucidating the components of purine and pyrimidine binary mixtures. For example, mixtures of adenine–cytosine (1:1), adenine–purine (1:1), cytosine–thymine (1:1), theobromine–theophylline (1:1 and 1:9), guanine–6-iodopurine (1:1 and 1:9), and thymine–uracil (1:1) have been identified unequivocally using these computer-assisted methods.

### Phosphorescence Spectrometry

The luminescence properties of purines, pyrimidines, and nucleosides have been extensively investigated, mainly from a physicochemical standpoint. These compounds generally have low fluorescence quantum yields, between 0.01 and 0.06, according to the molecule, in glycol–water (1:1), pH 7, and at a low temperature (77 K). The fluorescence intensities of purines and pyrimidines are practically nil or very weak at room temperature, preventing the analytical use of this method.

In contrast, the phosphorescence quantum yields are significantly higher, and thus low-temperature (77 K) phosphorescence (LTP) and solid-surface room-temperature (298 K) phosphorescence (RTP) have been applied to the analysis of purines and pyrimidines. The preferred technique is RTP because it is rapid, simple, and sensitive and avoids the use of the expensive cryogenic equipment that is needed in the case of LTP. A variety of pH conditions, heavy ions ( $I^-$ ,  $Tl^+$ ,  $Pb^{2+}$ ,  $Sm^{3+}$ , etc.), and solid substrates (cellulose, silica gel, aluminum oxide) have been studied. Optimal conditions have been selected according to the relative enhancement effects of pH, heavy ions, and solid substrate on the RTP signal of purines and pyrimidines. In most cases, thallium ions, and filter paper as the solid substrate, are found to provide good analytical results, with the optimal pH depending on the  $pK_a$  value of the compound. Linear calibration graphs cover two to four orders of magnitude of concentration. The LODs for RTP are relatively low, ranging between  $\sim 40$  pg and 19 ng, according to the particular purine or pyrimidine. Binary mixtures of purines and pyrimidines have also been determined using synchronous RTP.

### Special Methods for Nucleotides

Nucleotides contain purines or pyrimidines in their structure (Figure 1). Nucleotide purines and pyrimidines have different and important functions in biological system. They act as the bases of genetic material (DNA and RNA). Nucleotide triphosphates (ATP, GTP, UTP, and others) are considered to be energy centers containing a linked chemical energy.

This energy can be transferred to many ‘inert’ compounds such as amino acids, lipids, and carbohydrates, which then can contribute to other anabolic or catabolic reactions. Many biochemical reactions are regulated by cyclic nucleotides, including cyclic AMP (cAMP) and cyclic GMP (cGMP), which have a role of second messenger within hormone functions (in animal world), and other substances similar to them, which act in plants, bacteria, and viruses. Some nucleotides are coenzymes and prosthetic groups of many enzymes – oxidoreductases ( $NAD^+$ ,  $NADP^+$ , FAD) – and can transfer groups. Also, nucleotides are contained in the structure of chlorophyll, vitamin B12, and coenzyme A SH. Other nucleotides are very important pharmacological compounds that are used to prevent the growing up and mitosis of cells, at different levels. As a result, the determination of nucleotide concentrations in various biological media constitutes an important aspect of many experimental biological projects and therapeutic applications.

Generally, the nucleotide concentrations are very low in biological systems, and those of cyclic nucleotides are more than 1000 times lower. The first step of nucleotide quantification is to extract them, by means of boiling buffers, strong acids (sulfuric acid, perchloric acid, TCA), *n*-butanol, or bromosuccinamide. The choice of the extractant depends on the biological material to be analyzed. Moreover, the extracted solution must be neutralized at a pH value optimum for maximum enzymatic activity. After their extraction, nucleotides can be determined either using bioluminescence methods (firefly and bacterial) or using radioassay methods (radioimmunoassay and binding-protein assay).

The firefly bioluminescence method enables us to determine ATP. Luciferin undergoes a reaction of oxidative decarboxylation at pH 7.75 in the presence of ATP, oxygen, and a firefly luciferase (EC 1.13.12.7), yielding oxyluciferin,  $CO_2$ , AMP, pyrophosphate, and light emission. At high levels of luciferin, the luminescence intensity is proportional to the ATP concentration. Besides ATP, firefly bioluminescence is also used to determine the concentrations of other nucleotides and of a large number of important biological compounds. In addition, the activities of many enzymes are able to produce or consume ATP in successive coupling reactions.

The bacterial bioluminescent reaction requires the contribution of the flavine mononucleotide (FMN) reduced form (FMNH), a long-chain aldehyde (tetradecanal), and oxygen. All these molecules produce an oxidative reaction in the presence of bacterial luciferase (EC 1.14.14.3), giving tetradecanoic acid, FMN, water, and light emission; under these conditions,

the luminescence intensity is found to be proportional to the FMNH<sub>2</sub> concentration. Other substances that produce or consume FMNH<sub>2</sub> and/or nicotinamide adenine dinucleotide reduced form (NADH) in successive coupled reactions can also be determined using the same bacterial bioluminescence method. Indeed, in the last case, hydrogen atoms are transferred from NADH<sub>2</sub> to FMN, forming FMNH<sub>2</sub> in a redox reaction.

The concentrations of cyclic nucleotides can be quantified by means of two different radioassays methods (radioimmunoassay and binding-protein assay). The radioimmunoassay method of cAMP and cGMP determination is based on competitive ligand binding. The tissue extract is first mixed with <sup>125</sup>I radioactive tracer nucleotide and then incubated with a specific cyclic nucleotide antibody at 4°C. The reactivity due to the antibody is measured and is found to be in inverse proportion to the concentration of the nonradioactive competing ligand. The binding-protein assay is based on the use of a binding protein, which is specifically associated with cAMP in competition with radioactive-labeled AMP. Radioimmunoassay has a greater sensitivity than the binding-protein assay.

In general, the bioluminescence methods are considered to be more sensitive, accurate, and precise than the radioisotopic methods. Moreover, the first methods are more appropriate than the second ones from an ecological standpoint.

## Introduction

Chemical analysis can be divided into three main groups according to the purpose and type of information required:

- *Qualitative analysis*. This concerns the identification of the analytes present in a sample being subjected to the chemical measurement process.
- *Quantitative analysis*. This aims to determine the amount or proportions of an analyte, atoms, or chemical groups in the material studied and, therefore, it provides a numerical response suited to the particular question raised.
- *Structural analysis*. This involves the elucidation of (bio)chemical structure pertaining to an individual analyte or sample.

These three concepts are not independent as they can be related through a scope hierarchy. Thus, quantifying an analyte entails prior checking to find out whether it is present in the sample concerned. In addition, the identification of other interfering species that might be present in the sample will also be of interest. Likewise, structural analysis relies on the qualitative and quantitative information previously obtained. The boundaries between the three analyses are not very clearly defined as they share some connotations.

Two different terms can be found in the literature when dealing with qualitative analysis although they present slightly different connotations. The word 'detection' is normally used to refer to a chemical measurement process for qualitative purposes, opposed to determination, which is reserved for quantitative analysis. 'Identification' is usually employed for qualitative analysis aimed at recognizing the analyte (or its reaction product) from some chemical or physicochemical properties. As it entails the use of a standard for signal comparison, it is more appropriate as an alternative to qualitative analysis from a metrological point of view.

Qualitative analysis is an emerging area in pure and applied chemistry as its main objective is to obtain the maximum reliable information from the sample with minimum cost, effort, and time. The success or failure of such analysis is largely dependent on the skill and judgment of the analyst. Sometimes it turns to be a difficult task as many of the tests are not clear-cut and cannot be easily interpreted, being thus of little value in the hands of unskilled analysts.

It is interesting to note that although the classical slant of qualitative analysis had declined in the last decades with the advent of instrumental analytical techniques (the qualitative potential of which is under-exploited), simple qualitative tests are extremely relevant nowadays. It can be understood on the grounds of the increasing demand for achieving consistency between delivered and required analytical information that tends to be of a binary nature to a large extent: presence/absence of an analyte, positive sample/negative sample, or yes/no response according to a previously established threshold value.

## Qualitative Chemical Information

The principal objective of the analytical problem-solving process is to ensure the representativeness of the information delivered in such a way that the differences between the information demanded by the client and that delivered by the laboratory are minimal. Indeed, the amount of information that analytical laboratories provide usually exceeds the client's real needs. In this way, the analytical problem is not properly solved. The characteristics of the expected analytical information have constantly evolved from the classical approach to the present approach, which can be summarized as follows:

- greater simplicity;
- a substantial portion is of qualitative nature or based on the production of global indexes;
- relevance of productive properties (costs, safety, and expeditiousness); and
- information generated *in situ*.

Clients are usually interested in rapid, low-cost but reliable overall indicators (such as yes/no responses). For example, timely chemical information with 10% uncertainty would be better than very accurate and precise information but delivered too late to make a correct, profitable decision. An environmental body may be interested in knowing if an industrial soil is contaminated with hydrocarbons rather than in obtaining a detailed list of the analytes, including those at extremely low concentrations with their corresponding uncertainties.

Qualitative chemical information is characterized by the following features:

- it is usually of a binary nature (yes/no);
- it also presents quantitative connotations;
- it requires the definition of new analytical properties although the classical ones are still valid in this context; and
- it is scarcely supported by metrological standards and guides.

## The Binary Response

The expected response from a qualitative analysis is of a binary nature: yes/no. However, the level of information of such a response can be rather different

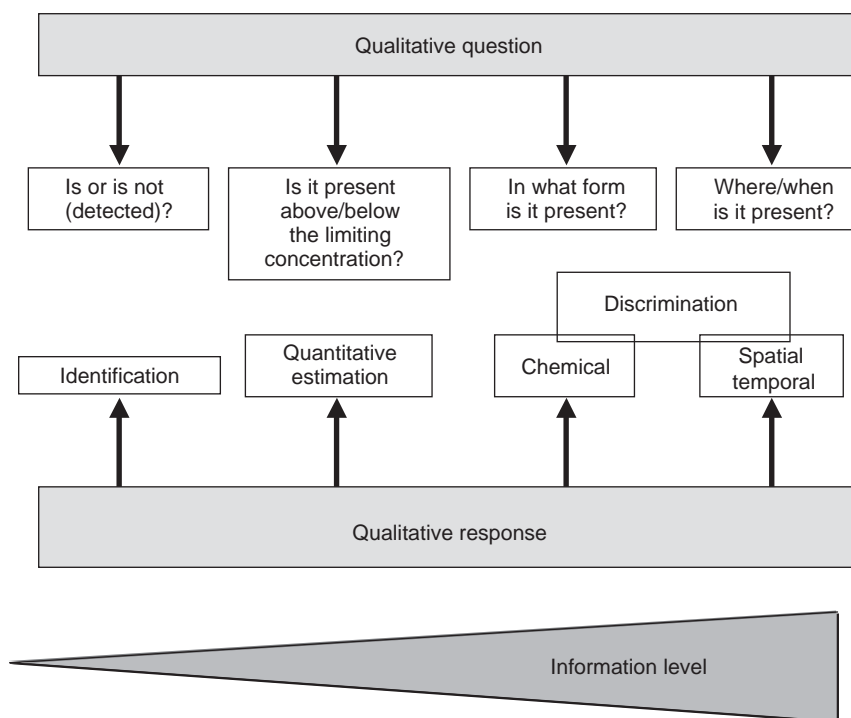

depending on the question raised on the sample; some examples are shown in **Figure 1**.

The lowest level of information corresponds to the identification of the analyte in the sample (is the analyte present/detected or not), thus being a prerequisite for the others. Sometimes, the laboratory may need to consider a concentration limit imposed by the client or legislation. The qualitative information given has more quantitative connotations than stated in the simplest question.

Even in its most simple possible form, the yes/no binary response can differ chemically, spatially, or temporally (third and fourth levels of information). Qualitative information can discriminate among the different forms in which an analyte may occur in a given sample (speciation). This chemical discrimination involves a multiple binary response (one per species potentially present). Finally, the highest level of information demands expands the binary response with temporal or spatial discrimination answering the question 'when' for dynamic objects or 'where' for heterogeneous ones.

## Quantitative Connotations

The quantitative connotations of qualitative information are derived from the data comparison carried out in response to an existing limiting

**Figure 1** Types of qualitative responses according to the information content they provide to properly answer the qualitative question posed by the client.

concentration/amount of analyte. It allows the laboratory to determine if a sample/object has the required quality. In this regard, three quantitative references can be clearly identified, namely: limit of detection, cut-off, and threshold/alarm limits. The limit of detection is an internal reference inherent in the chemical measurement process. The cut-off limit is established by the analyst/organization in setting a given probability level to ensure the obtainment of a correct binary response. The threshold concentration is the highest or lower level established by the client or legislation to be used in deciding whether or not the sample warrant assignment of a given attribute (e.g., contaminated, light, etc.). According to these definitions, the limit of detection must be lower than the other two references to allow detection/identification. The cut-off concentration must exceed the limit of detection as it involves a higher probability level to make the detection error-free. Finally, any externally imposed limit should be greater than the other two to ensure a reliable binary response. The higher the difference between the cut-off/threshold concentration and the detection limit, the more reliable will be the qualitative information given. The internal (cut-off) reference can always be established while the external one (threshold concentration) may or may not exist, coincide, or even differ with applicable legislation or client's specific needs.

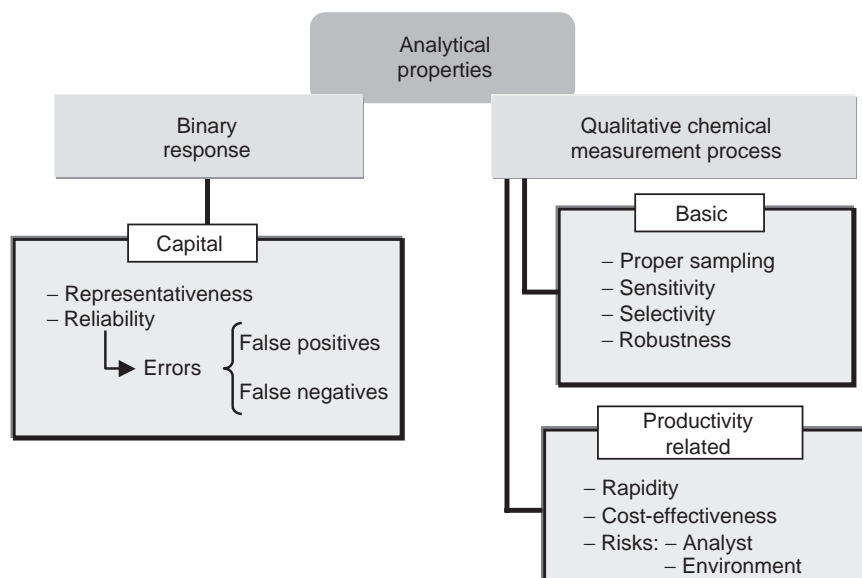

### Analytical Properties

The analytical properties that characterize a quantitative analytical process cannot be directly extrapolated to qualitative analysis owing to the peculiarities

of the binary yes/no responses. Some adaptations are needed as can be seen in Figure 2.

**Representativeness** The binary yes/no response should be representative of the test sample, the object, the analytical problem raised, and the information requested. This property is especially significant when tackling the problem with the imposed limits and threshold in mind. Proper sampling is the main requirement of this crucial property.

**Reliability** It is rather difficult to use the accuracy and precision concepts as these capital and basic properties are closely related in qualitative analysis. Their combination has produced a new property called reliability, which is defined as the proportion (percentage) of right yes or no answers provided by individual tests carried out on  $n$  aliquots of the same sample to identify an analyte or a family of the analytes. This definition represents the positive side of the errors in qualitative analysis: false positives and false negatives. The reliability of the binary response is not an independent property as it strongly depends on the basic properties of sensitivity and selectivity. Moreover, it is in contradiction with productivity-related properties. Reliability is equivalent to certainty and, in quantitative analysis, the uncertainty of a result is a parameter associated with reliability. Indeed, the term is included in the definition of traceability as every experimental datum is affected by specific variations or doubts. As it directly affects the quality of an analytical result, it is necessary to find out an equivalent method to express uncertainty in qualitative analysis. The term unreliability can be

**Figure 2** Analytical properties in qualitative analysis.

proposed to characterize the range of responses where the errors are produced. It is a property of binary yes/no response and it is also expressed by a measurand response range. Both reliability and unreliability define the same capital analytical property in the opposite sense.

**Sensitivity** It expresses the ability of a qualitative method to detect small amounts of the analyte in a sample to produce the binary yes/no response. It can also be defined as the ability to discriminate yes/no responses for samples containing similar amounts of analyte. From the different parameters that can be used in quantitative analysis, the only one relevant in qualitative analysis is the above-mentioned limit of detection.

**Selectivity** This property may refer to a single analyte (viz., the ability of the qualitative method to produce results that are exclusively dependent on the measurand for its identification) or to a family of the analyte and the absence of interferents from components other than the target compounds. Selectivity is a crucial support to reliability: the higher the selectivity, the better the certainty.

**Robustness** It is a basic analytical property of a qualitative method that describes its resistance to change the binary yes/no response when applied to individual amounts of the same sample under slightly different experimental conditions. The ultimate purpose is to find out the experimental weakness of the method, viz., the actual factors influencing qualitative responses. This property is directly related to certainty of identification (reliability).

**Productivity-related properties (rapidity, cost-effectiveness, and risks)** Although they are only occasionally considered in metrological approaches (validation), a systematic consideration is mandatory because of their practical impact. They can imply a serious limitation for routine application of the qualitative method even though it shows high levels of capital and basic characteristics. If the method is too expensive, slow, or involves risks, it cannot be appropriate to solve the analytical problem addressed (fitness for purpose).

The hierarchical foundation, and contradictory and complementary relationships among analytical properties are quite applicable in this context.

## Errors

The errors contained in qualitative information are specifically called 'false positives' and 'false negatives'. A false positive arises when the signal

from a sample containing the analyte at a level below the reference concentration yields a 'yes' response. A false positive also arises when the signal belonging to a compound different from the analyte is wrongly assigned to the target compound. On the other hand, a false negative results from the signal for a sample containing the analyte at a level above the reference concentration provides a 'no' response. Therefore, the assumption is made in rejecting a signal for a sample containing the analyte in the mistaken belief that its concentration is lower than the limit established. The relative concentration of the analyte in relation to the reference concentration affects the type of error made; if the concentration is slightly higher than the reference, then a false negative is expected while for concentrations lower but close to this reference value, false positives are to be expected.

The relevance of such errors depends on the particular analytical problem. In general, all positive results from a qualitative test will be systematically confirmed by a conventional chemical measurement process when any error made may have a significant social or economical impact and, therefore, their practical impact in the decision-making is low. However, quality assurance of negative responses is crucial, as their practical effects are more relevant. Indeed, they are especially serious when detecting or identifying a toxic chemical in environmental, food, or clinical samples as no confirmatory step is carried out.

## Classical versus Instrumental Qualitative Analysis

Qualitative analysis can be classified according to a variety of criteria. One of them considers the analytical technique used and, therefore, qualitative chemical measurement processes can be divided into two main blocks: classical and instrumental qualitative analyses. Their main characteristics will be briefly discussed below.

### Classical Qualitative Analysis

Classical qualitative analysis uses human senses (as sensors) and the brain (to process the signals) to detect the presence of an analyte that was previously subjected to a (bio)chemical or immune reaction with the view of yielding a product clearly identified from a well-defined change.

Identification is carried out by sensual comparison, possibly but not necessarily using a reference scale (e.g., test strips) from which the operator will obtain semiquantitative information. Such is the case with pH, active chlorine, and glucose measurements based on reagent strips.

The main limitations of classical qualitative analysis can be summarized as follows:

- low sensitivity due to limited capacity of the human operator to detect small changes and, hence, low discrimination among signals;
- the less variety of information that can be derived; and
- reliability relies on the chemical reaction(s) involved.

The chemical measurement process used in classical qualitative analysis can be either a direct or a systematic procedure using sequential separations to indirectly raise sensitivity and selectivity. The qualitative analysis also differs depending on whether a single analyte, a family of analytes, a small group, or a wide range of groups are to be identified.

There are three generic approaches to the identification of analytes in complex mixtures, namely:

- Direct individual identification of each analyte or family using highly selective and sensitive tests.
- Individual identification following systematic separations (precipitation, liquid–liquid extraction, ion exchange, etc.) to obtain spatially discriminate species (individually or in groups).
- Individual identification of each analyte in different sample aliquots, which may be subjected to a simple separation technique, included in a pre-established operational sequence.

Analytes can be identified using a variety of reagents and the many different combinations of analyte–reagent resulted in a wide range of situations of variable complexity. Such combinations dictate the type of identification reaction to be used in each case. Thus, inorganic reagent and analyte combination involves a precipitation, redox, or complex formation reaction; the organic reagent–inorganic analyte combination leads to a colored or fluorescent chelate formation; and in the organic or biochemical analyte combination, the identification reaction is of organic or biochemical type.

The reagents typically used in classical qualitative analysis can be grouped into three main categories:

- *Identification reagent.* Compounds of inorganic, organic, biochemical, or immune nature that give a reaction, the external effect of which can be readily detected by the human senses (precipitate, gas, color, change, etc.). The test associated should possess adequate sensitivity and selectivity, directly or after separations included in an analytical scheme.
- *Group reagents.* They affect the separation of the analyte(s) present in a sample in order to increase the reliability of individual identification.
- *Masking reagents.* They prevent interference from other species potentially present in the sample or isolated group of analytes. They should never significantly disturb the main analytical reaction.

### Instrumental Qualitative Analysis

Instrumental qualitative analysis converts a physico-chemical property of the analyte (or its reaction product) into an analytical signal that can be measured by an instrument with the view of identifying it. It is, therefore, more reliable and more widely applicable than the classical approach. Notwithstanding this, not all instruments are equally capable of providing reliable identification. In this context, reliability can be understood as a combination of the selectivity and the amount of information content of the response that they provide. For example, the use of a single signal (e.g., absorbance) obtained using a single instrumental parameter (e.g., wavelength) obviously provided less reliable qualitative identification than multiple signals recorded using many different instrumental parameter values (e.g., the bands in an infrared absorption spectrum).

Instrumental analytical techniques applied to qualitative analysis can be divided into three main categories:

- *Group 1.* They are useless in qualitative analysis as they provide general responses, usually one shared by many analytes (e.g., balance or piezoelectric sensor). This signal can be, however, altered in some way to increase its selectivity (e.g., thermogravimetry or piezoelectric sensor coated with selective sorbent material).
- *Group 2.* These instruments give scarcely selective responses (e.g., photometers), but can be improved by analyte derivatization to products with different spectral characteristics. Higher reliability can be achieved by using more selective techniques (e.g., fluorimetry). Moreover, online coupling of these instruments with continuous column chromatographic techniques results in greater selectivity as it permits the separation of the analytes prior to detection.
- *Group 3.* It includes highly selective instruments (atomic absorption and emission spectroscopies) or instruments providing information that contains many well-resolved signals obtained using multiple instrumental parameter values (infrared spectroscopy or mass spectrometry). Their use as detectors in chromatographic techniques has given

rise to the so-called hyphenated techniques, which provide significantly increased reliability in identification. This analytical property can be substantially improved by the joint use of the information provided by one instrument of the second group and another from the third group. The highest level of reliability results from the combination of a separation technique and two or more instruments of the second, or better, third group.

In this context, the fitness-for-purpose should be borne in mind, i.e., the selection of the most appropriate instrument on the grounds of the actual client's information needs rather than the selectivity provided by a given analytical technique.

## Modern Approach to Qualitative Analysis

Analytical information delivered by the laboratory should be coherent with that demanded by the client in order to properly solve the social problem raised. As was previously stated, qualitative information represents a substantial portion of the information required. Therefore, modern qualitative analysis needs to consider what the main objectives of the analysis are, externally imposed by the client or regulation needs. Under this consideration, the two types of qualitative analysis shown in **Figure 3** can be distinguished, namely: qualitative analysis for sample qualification/classification and qualitative analysis for analyte identification.

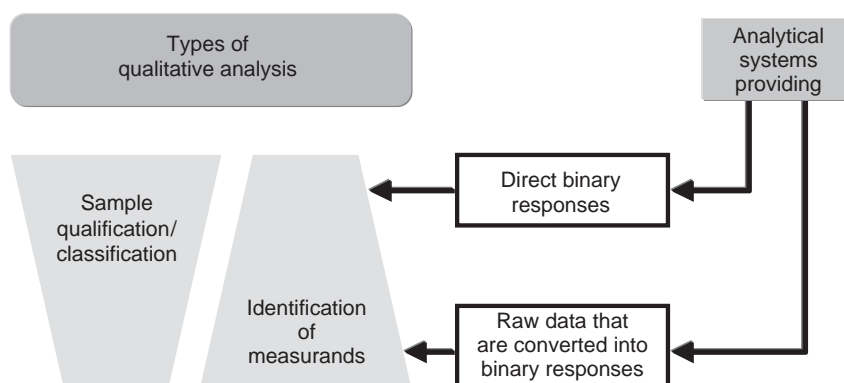

The difference is established according to the possible questions asked by the clients and not on the analytical technique used. The main objective of the former is to provide a rapid, reliable screening of the samples on the grounds of previously established criteria (cut-off or threshold values fixed by the

laboratory or the legislation, respectively). The second type permits the identification of an analyte or a family of the analytes as an answer to questions such as 'is this compound the analyte?' or 'is it detected in the sample?' using powerful spectroscopic and chromatographic tools. The two types of qualitative analyses are not independent, however. Identification/quantitation of the analyte is usually required prior to sample qualification/classification (viz., estimation of the concentration of a given analyte as regards the previously established cut-off or threshold).

As can be seen in the figure, qualitative analysis can be implemented using two general analytical tools. On the one hand, there are analytical systems, such as test kits, that provide the binary response in a direct way, which are more convenient for sample qualification/classification. On the other systems based on the use of analytical techniques providing raw data, which are further processed and converted into binary responses, are more appropriate for analyte identification.

### Qualitative Analytical Systems for Sample Qualification/Classification

Fast and reliable analytical processes designed for sample qualification/classification are generally known as sample screening systems. The term refers to analytical methodologies intended to identify and select a group of samples, from a starting set, in relation to a specific property of the sample, in order to provide a requested information (for example, if they contain one or more analytes above a preset concentration level). These straightforward, responsive analytical systems allow those samples to be filtered out, minimizing the preliminary operations of the chemical measurement process. Only those samples providing a positive response in the screening step will be subjected to the conventional analytical

**Figure 3** Types of qualitative analysis according to the objective of the analysis and their relationship with qualitative analytical systems.

process, both for confirmation and increasing the information level.

Test methods are also useful for sample qualification/classification. They can be defined as a combination of a test tool and procedures for detection and determination, which do not require complex sample treatment, sophisticated instruments, or complicated data treatment. In most cases they involve self-contained, single-use tools. The reagents and additives are supplied as ready-for-use solutions (in ampoules or droppers) or immobilized on a solid support such as paper, silica gel, or polyurethane foam. They are expected to be of reduced size and weight, easy to use, having speed of operation, and independent power supply. Either visual or colorimetric detection for comparing and assessing color can be normally used. Advances in other areas such as microelectronics, physics, and technology have become feasible to build portable, pocket size instruments such as photometers, reflectometers, luminometers, and turbidimeters. The most relevant applications of such devices are the determination of organic and inorganic species in water, monitoring of toxic gases, detection of vapors, alcohol, and narcotics, and the determination of glucose in whole blood.

Qualitative analysis for sample qualification/classification can be divided into two main groups depending on whether the information required by the client is related to one single chemical species or not. Indeed, sometimes the questions are related to a quality of the sample, which may not only be defined by single chemical species, for example, 'is this wine a Merlot?', is the hydrocarbon index above a threshold value?'. In these cases, the response expected from the analytical process is a global or total index. A global index can be defined as a measurand that describes a group (family) of chemical or (bio)chemical species from millions to few of them that have similar nature/structure (total fat), operation behavior (chemical oxygen demand), or both (total polychlorinated biphenyls). Calculation of global indices depends on the raw data provided by the qualitative chemical measurement process followed. One group provides a single primary signal at a fixed instrumental parameter with different contributions of the different measurands of the target group. The other group gives discriminate signals for each analyte that needs further conversion into a global index.

### Qualitative Analytical Systems for Identification of Measurands

Methodologies intended for both analyte(s) identification in complex samples and multideterminations can also be considered within the framework of

qualitative analysis. These systems use conventional sample treatments and/or powerful identification techniques (e.g., Fourier-transform infrared spectroscopy, inductively coupled plasma-mass spectrometry, nuclear magnetic resonance), with or without analyte separation using either chromatography or electrophoresis. The last alternative enhanced sensitivity and selectivity through (a) separation of the monitored compounds from matrix components and separation of the analytes themselves, which can be expanded using multidimensional or multimodal chromatography; and (b) increased identification power by using hyphenated techniques.

Qualitative procedures for identification of measurands have been successfully applied in different areas of interest. They are widely variable in the sample treatment proposed, which is directly related to the nature of the sample and analytes as well as the detector used.

## Introduction

From the earliest days of mass production, in which pikes of equal length and standard manufacture in the New Model Army of Oliver Cromwell is a well-documented example, there has been a clear desire to ensure that the output of a process is as it was intended. A manufacturer of a physical product has particular specifications and tolerances that allow testing of the product before it is unleashed on the unsuspecting public. The provider of an analytical service is under no less an obligation to provide a quality product, but it may be less obvious what the definition of quality in that product is. The problem is that each analytical result is a unique entity whose true value is usually unknown.

The analytical laboratory, in setting up a quality assurance scheme, must therefore employ strategies that allow it to infer quality in a result that is released to a client. This section is an overview of the types of approach that can be employed and some of the methodologies employed by laboratories to ensure, as far as possible, their products – analytical results – are of high quality.

## Definitions of Quality

The literature is not at a loss for definitions of quality:

- Delivering to a customer a product or service that meets the specification agreed with the customer, and delivering it on time.
- Satisfying customer requirements.
- Fitness for purpose.
- Getting it right the first time.

While none of these seems to be quite right for analytical science, the intent is entirely clear. The analyst must deliver to his or her client a result that conforms to agreed specifications and can be used for the client's intended purposes. How the analyst does that is by implementing a regime in the laboratory that provides such assurances about the results being produced.

Different aspects of quality assurance are defined by the level in the organization that they are concerned with. The Association of Official Analytical Chemists has offered the following:

1. *Quality system*. Laboratory activities aimed at producing accurate work and a high-quality work product.
2. *Quality control*. Planned activities designed to provide a quality product.
3. *Quality assurance*. Planned activities designed to ensure that quality control activities are being properly implemented.

Thus, quality control (QC) is overseen by quality assurance (QA) and both are part of the laboratory's quality system. In these definitions, planned activities

**Figure 1** Analysis viewed in operational terms as a process operating on inputs to produce outputs. Quality control inspects (A) the process, initiating improvement, and preventative action, or (B) the output that triggers corrective action when nonconforming product is detected.

refer to a systems approach to management in which the operations of the enterprise may be viewed in terms of inputs, processes, and outputs, with the possibility of inspection of outputs and processes and hence feedback causing improvement in the quality of the product (Figure 1).

Hopefully, by inspection of the process (Figure 1A) potential concerns may be identified and dealt with before results are obtained. Traditional QC inspects the product (here the results) and nonconforming output initiates feedback to the process (Figure 1B). As discussed above, analytical science rarely has the luxury of knowing whether the output is of sufficient quality until the client complains.

## Measures of Quality in a Laboratory

The reputation for quality of a laboratory rests on a number of factors that may include: the scientific reputation of the laboratory; observed work practices; staff qualification and experience; a history of satisfactory achievement; good results in QA audits and reviews; and accreditation to international guides and standards.

In a survey of analysts the top rating indicators of quality were the use of validated methods and the use of reference materials followed by participation in proficiency testing and quality audits. The Valid Analytical Measurement program of the Laboratory of the Government Chemist in the UK lists six aspects of a quality laboratory that mirrors the list given above:

- work to an agreed customer requirement;
- use validated methods and equipment;

- use qualified and competent staff;
- participate in independent assessment of technical performance (proficiency testing);
- ensure comparability with measurements made in other laboratories (traceability and measurement uncertainty);
- use well-defined quality control and quality assurance practices.

The assurance of quality in the analytical laboratory differs from that in manufacturing industry in that although statistics are used extensively, and the application of the principles of statistical process control have grown in recent years, the scope of QA activities is much wider.

## The Basis for Quality Analytical Measurement

### Use of Validated Methods

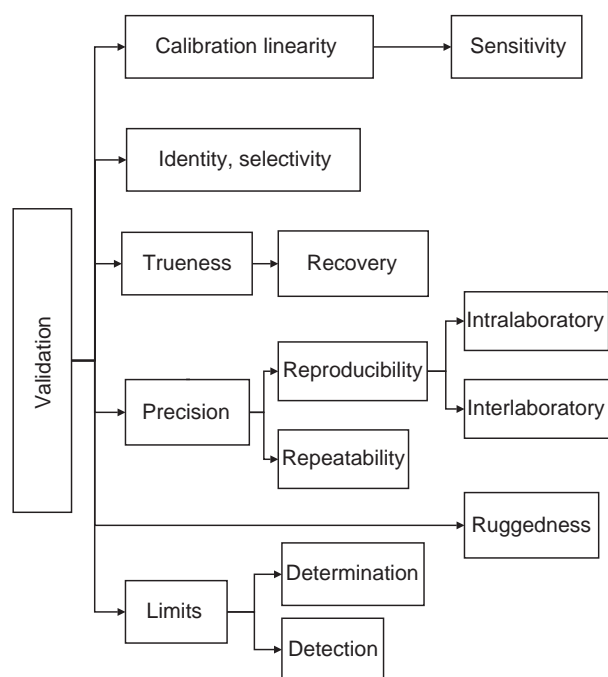

The use of any analytical method implies that the method, if employed properly, will yield an acceptable result. However, a client of an analytical service is entitled to have some documentary evidence that this assertion is true. Method validation (q.v.) is a lengthy process that is applied to a new method after development to provide evidence that the method will indeed produce results to satisfy the client's requirements. Figure 2 is a schematic of the different aspects of a method that may be considered during method validation.

Standard methods of analysis, for example, those published by American Society for Testing and Materials or International Organization for Standardization (ISO), have the imprimatur of the organization and have been developed and validated for use in field laboratories. They have usually been subjected to a method performance study, a kind of interlaboratory study (q.v.), which establishes repeatability and reproducibility precision and possibly method bias. The published methods also indicate the range of concentrations for which the method can be used, and the detection limit.

It is the responsibility of any laboratory to demonstrate the validity of the method used. Referring to some third party validation is sufficient if there is a statement that the laboratory can follow the method to ensure the maintenance of the validation. This requires some measure of verification to show, for example, that the analyst in the laboratory can achieve the repeatability precision indicated in the method.

Although there has been a move to requiring the demonstration of a target measurement uncertainty,

**Figure 2** Schematic of the aspects of an analytical method that may be assessed during a method validation.

there is much legislation in countries around the world that requires the use of a specified standard method.

### Assessment of Measurement Uncertainty

It is now understood that an analytical result comprises not only a number and its units but also the measurement uncertainty (q.v.). As part of accreditation requirements, and also as a proper approach to providing a quality result, the measurement uncertainty should be assessed and quoted. The fitness for purpose of the result may determine the rigor with which the measurement uncertainty is estimated, but however carefully it is determined the quoted expanded uncertainty (the range within which the true value may be found with given probability) should be correct. This means that the expanded uncertainty should be sufficiently wide such that the quoted probability is at least fulfilled. Perhaps a more detailed assessment of uncertainty would reduce the range, but it should never be underestimated. Particularly, the reproducibility from a standard method is not sufficient as a measurement uncertainty, although it may comprise the largest component.

### Traceability of Measurements

By giving a result in a particular unit implies that the result may be traced back to the definition of that unit. The use of the unit mol,  $\text{mol dm}^{-3}$ , or kg

implies that the measurement result is traceable to the definition of the unit of amount of substance, amount of substance concentration, or mass, respectively. The traceability chain is established by a series of calibrations using calibrators whose quantity values are themselves traceable. In a field measurement, the calibrator is usually an in-house standard that is traceable to a certified reference material. Without explicit traceability the result is only as good as the calibrator used, which may mean that the laboratory gives results that are traceable to values carried by material found only in that laboratory.

## Approaches to Quality Management

### Accreditation

Although accreditation *per se* does not guarantee the quality of a given result, it is clear that a laboratory that has been through a careful scrutiny of its operations and has been assessed against an international standard must be in a better position to claim quality of results. National or international bodies themselves accredited and members of the International Laboratory Accreditation Cooperation conduct assessments and confer accredited status to laboratories under their jurisdiction. Legislation frequently requires laboratories undertaking analysis to be accredited to International Standards Organization (ISO)/International Electrotechnical Commission (IEC) 17025. Here, two international standards are briefly discussed, ISO/IEC 17025 and Good Laboratory Practice (GLP) guidelines issued by the United States Food and Drug Administration (US FDA) and European Union.

**ISO/IEC 17025** This standard, entitled 'General requirements for the competence of testing and calibration laboratories,' has two parts, one relating to management structures that covers the ISO 9000 series of quality practices, and the second to practical aspects of testing and calibration. The standard specifies that the laboratory shall use validated methods, determine measurement uncertainty, and ensure the traceability of its results. The laboratory shall also report measurement uncertainty when the client requests it and when it is applicable; for example, when a result must be compared to a statutory limit. This standard also allows the analyst to offer interpretations and advice where appropriate.

**Good Laboratory Practice** In response to concerns in the mid-1970s about the veracity of reports on the safety of clinical medicines, the US FDA issued regulations in 1978 to prescribe principles of GLP

that should be applied to the nonclinical safety testing of test items contained in pharmaceutical products, pesticide products, cosmetic products, veterinary drugs, as well as food additives, feed additives, and industrial chemicals. These regulations cover much the same areas of management and methodology of laboratory testing as ISO/IEC 17025, but are aimed specifically at laboratories conducting nonclinical research, rather than general testing and calibration. There is an emphasis on the managerial structure (particularly with regard to QA), record keeping, and audit control.

### **Other Management Approaches to Ensuring Quality**

Before turning to specific measures of QC in the laboratory, a number of possible approaches that are available, if not widespread in analytical science, will be discussed.

**Peer review/visitors** Common in government and academic institutions, but not in the commercial sphere (for obvious reasons of confidentiality), the use of senior personnel from a similar organization to conduct reviews of a laboratory's operation is one way of receiving useful advice. The review rarely goes down to the day-to-day operation and often focuses on the more strategic aspects of the laboratory.

**Benchmarking** Akin to peer review, an organization can benchmark itself against what is seen as the best available practice. Internal personnel or an outside consultant prepare a report in which the procedures of the organization are compared against those of the target best-practice organization. As with peer review, benchmarking tends to concentrate on the bigger picture of the laboratory's operations.

**Total quality management** Total quality management is a popular approach to organizational management that can be adapted to a research-oriented analytical laboratory. It is considered a leadership style of management that promotes and cultivates a 'one team approach' by accepting risk taking and with an emphasis on continuous learning and improvement. One aspect that does promote a scientific approach to quality is the use of objective monitoring of progress using statistical tools. Brainstorming sessions of all the staff are encouraged to provide new ideas that can be tried and evaluated. It is clear that this approach is more suited to an R&D environment rather than the routine application of a standard analytical method.

**Project management** Project management is a structured approach to work that views a project in terms of defining, planning, implementing, and completing. There is use of project tools such as Gantt charts, with milestones and the attendant monitoring and reporting. Project management emphasizes a full specification of the task and communication between groups. Again this is suited to the management of large research efforts rather than day-to-day analysis.

**Six sigma** Six sigma is one of the more recent popular approaches to QA that is based on a tight statistical approach to the production of a product. The name arises from a desire to limit the tolerance of a product to plus or minus six standard deviations and thus have only 3.4 defects per million. (This is the fraction outside  $\pm 4.5$  standard deviations from the mean; the method allows for some measurement uncertainty.) In order for the statistics to hold, the system must be in statistical control and the defects must be random and normally distributed. There is a heavy reliance on control charts and the system is built around what to do if there is evidence for nonconformity. For a nonconforming product six sigma institutes an approach with the acronym DMAIC – define, measure, analyze, improve, control. This has been implemented in some organizations, such as pharmaceutical companies, which produce large volumes of chemicals. However, strict statistical control of chemical products is not always easy, and considerations of the measurement process also needs to be taken into account.

## **Tools for Quality Control**

So far this article has concentrated on management approaches to quality. This is appropriate, because no amount of QC at the laboratory bench can overcome shortcomings in the QA system or the culture of the organization. However, once management is committed to producing quality results what are the tools available to help the organization?

### **Cause and Effect Diagrams**

At the planning stage, cause and effect diagrams can be useful in analyzing the operation of a laboratory. Together with Pareto charts and other such indicators they can allow management to pinpoint areas that may be of concern. In particular, in the analytical laboratory the use of a cause and effect diagram (also known as an Ishikawa or fish bone diagram) can form the basis of the estimation of measurement uncertainty. It is applicable to analytical science because most measurement results require calculation

and are based on a measurement model that can be used as a basis of further dissection of the method. As a simple example, consider a titration in which the amount of substance concentration of the unknown ( $M_{\text{unknown}}$ ) is determined from the endpoint volume of the titration ( $V_{\text{titration}}$ ), and the volume ( $V_{\text{standard}}$ ) and amount of substance concentration ( $M_{\text{standard}}$ ) of a standard solution:

$$M_{\text{unknown}} = \frac{M_{\text{standard}} \times V_{\text{standard}}}{V_{\text{titration}}} \quad [1]$$

where the standard solution is made up by weighing an amount ( $m$ ) of a standard (molar mass  $MW$ ) of given purity ( $P$ ) and making up to a volume  $V$ :

$$M_{\text{standard}} = \frac{m \times P}{V \times MW} \quad [2]$$

A consideration of the method is now broken down to investigation of the influence factors of each of the three components of  $M_{\text{unknown}}$ . They are arranged on a cause and effect diagram as shown in Figure 3A.

Each branch of the diagram is then elaborated to include individual influence factors. It is possible to continue the ramification until all influence factors have been identified (Figure 3B). A number of components may be identified as contributing to the re-

peatability or reproducibility precision. It may be possible to use validation data to provide much of the measurement uncertainty estimates.

The great advantage of the bottom-up approach to measurement uncertainty, even if precision data are to be used extensively, is that the analyst is made to consider the experiment in detail and he or she must understand the analysis and components of uncertainty. This may provide a useful insight into possible improvements that could be made to lower the combined uncertainty. Influence factors that are estimated to contribute less than, say, 20% to the measurement uncertainty can really be ignored when finding aspects for improvement. The contributions to measurement uncertainty can be displayed on a Pareto chart, which shows the individual components and cumulative effect. An example for a quantitative nuclear magnetic resonance (NMR) study is shown in Figure 4.

In this example, the intralaboratory precision is the greatest contributor to the uncertainty. There would be nothing gained, for example, in performing the mass measurements on a more precise balance.

### Control Charts

As part of the day-to-day operations of an analytical laboratory in which the same type of analysis is performed, it is usual to include check samples in the batches of unknowns. These are made from reference materials whose quantity values are known. If the analysis of this material correctly recovers the assigned quantity value within measurement uncertainty then the process is considered to be in control. Further information may be obtained by tracking these analyses over time, using control chart methodology developed during the early and mid-twentieth century for QC in the manufacturing industry.

**Figure 3** Cause and effect diagram of a titration in which the standard solution is made up from pure solid. (A) Initial diagram with elements from the measurement model (see eqn [1]). (B) Diagram with expanded influence factors.  $T$ =temperature,  $s_r$ =repeatability,  $cal$ =manufacturer's calibration (see also eqn [2]). The mass measurements done by difference will contribute only linearity of calibration to the uncertainty labeled 'cal'.

**Figure 4** Pareto chart of contributions to the analysis of the purity of the agrochemical glyphosate by quantitative NMR. MW=molecular weight, P=purity,  $\sigma$  (intra)=intralaboratory standard deviation.

**Shewhart mean and range charts** A Shewhart means chart plots the average of determinations of a check sample against time. The time scale is chosen by the analyst and is whatever is most appropriate to the operation. If the interest is the long-term stability of the analysis, check samples analyzed each day may be averaged over a week, or if the batch-to-batch variation is of interest, the means of two check samples included in each run may be averaged. It is recommended that a sample size of at least two and no more than six should be chosen. The essence of the means chart is that the plot includes the expected mean and upper and lower lines that chart the expected limits of the results. If the system is in statistical control with mean  $\mu$  and standard deviation  $\sigma$  then the results should scatter about  $\mu$  with only five in every hundred results falling outside  $\pm 2\sigma/\sqrt{n}$  (where the sample size is  $n$ ), and three out of every thousand falling outside  $\pm 3\sigma/\sqrt{n}$ . Inspection of a means chart allows a check for any outliers or trends in the data. It is recommended that if two consecutive means fall outside  $\pm 2\sigma/\sqrt{n}$  (the so-called upper and lower warning limits) or if a single mean is outside  $\pm 3\sigma/\sqrt{n}$  (upper and lower control limits), then the analysis should be considered to be out of control and its use should be suspended followed by a careful investigation of possible causes of the problem. **Figure 5** is an illustrative means control chart in which the analysis has given two consecutive results over the upper warning limit. There are alternative formulae for the warning and control limits and more extensive rules for dealing with potentially out of control data, which may be found in the literature.

If the true mean ( $\mu$ ) and standard deviation ( $\sigma$ ) are not known the statistical parameters may be obtained from careful analyses of nonroutine samples to give results that may be accepted as within statistical control.

**Figure 5** A Shewhart means chart. The final two points are above the upper warning limit and would trigger suspension of the analysis and investigation of the process.

In addition to the mean being within statistical boundaries, the range of the data should also be monitored as a check of the process standard deviation. From the population standard deviation, or average range of a training set of data, it is possible to calculate expected ranges (i.e., maximum minus minimum values in the sample) and so construct upper and lower warning and control limits for the range. These are not symmetrical and must be obtained from tables.

**CuSum charts** In a CuSum chart, the cumulative sum of the difference between the mean result ( $\bar{x}_t$ ) and the target value ( $\mu_0$ ) is plotted against time. For a system in control, results are distributed about  $\mu$  and so the expectation of the difference is zero. A bias, however, will cause an accumulation of differences that can be detected. In the days of graph paper a V-shaped mask was placed over the graph with points outside the V indicating a system out of control. With calculations largely done in spreadsheets, the following calculations are performed. For a positive shift from the mean

$$S_t^+ = \max \left\{ 0, S_{t-1}^+ + \frac{\bar{x}_t - (\mu_0 + k\sigma_{\bar{x}})}{\sigma_{\bar{x}}} \right\} \quad [3]$$

where  $\sigma_{\bar{x}}$  is the standard deviation of the mean,  $k$  the allowable change in one measurement period expressed in standard deviations of the mean (usually  $k=0.5$ ), and  $S_0=0$ . The equivalent equation for a negative shift is

$$S_t^- = \max \left\{ 0, S_{t-1}^- + \frac{\bar{x}_t - (\mu_0 + k\sigma_{\bar{x}})}{\sigma_{\bar{x}}} \right\} \quad [4]$$

$S_t^+$  and  $S_t^-$  are plotted against time, and when either goes over a threshold  $h=4$  the process is considered out of control. **Figure 6A** shows a Shewhart means chart for a measurement of motor octane number over a number of months. Although it appears that the results are consistently biased above the expected mean, apart from the last point, no result has triggered action based on the warning and control limits. A CuSum chart, however, does reveal a statistically significant trend (**Figure 6B**) when the value of  $S_t^+$  goes above  $h$  in July and then September and after.

**Average run length** A question that may arise in connection with the use of CuSum, mean, and range charts is ‘how soon will I discover that the mean has changed?’ An analysis that returns a higher value because of some change in the application of the method will have a greater probability of crossing the upper warning and control limits of a means chart

**Figure 6** Monthly data from analysis of a fuel for motor octane number (A) Shewhart means chart of duplicate results. The mean, warning and control limits are shown. (B) CuSum chart of  $S^+$  calculated from eqn [3], showing the limit  $h=4$  is exceeded in July.

than the expected 2.5/100 and 1.5/1000, respectively. The average run length (ARL) is how many points on average will follow a change before it is detected. A trivial example is that if the mean changes by  $3\sigma/\sqrt{n}$ , when it now sits on the upper control limit, on average it will take 1.5 points (i.e., 1 or 2 points) to go above the control limit. For a change of  $1\sigma/\sqrt{n}$  the ARL is 44. This highlights a characteristic of a means chart; it is much more sensitive to large changes than small changes in the process mean.

CuSum, as we have seen, is more responsive to a small bias in the results. The ARLs for different changes in the mean are tabulated in Table 1. When the shift of the mean reaches 2.5 standard deviations either method can detect the change quickly.

## Qualimetrics

In recent years, a branch of chemometrics devoted to quantitative methods of quality evaluation has been given the name qualimetrics. It covers the tools and approaches described in this article and takes an overall view of the quality issue, including customer perception as well as measurable quantities. Multivariate methods have also found their way into

**Table 1** Average run length rounded up to the next integer for a shift of the mean result by the given amount in numbers of standard deviations of the mean, for CuSum and Shewhart means charts

Shift in the mean ( $/\sigma_{\bar{x}}$ )	ARL (CuSum, $h=4$ )	ARL (Shewhart, $3\sigma_{\bar{x}}$ )
0	336	371
0.25	75	282
0.5	27	155
0.75	14	82
1.0	9	44
1.5	5	15
2.0	4	7
2.5	3	4
3.0	3	2
4.0	2	2

qualimetrics. Measurements that give large numbers of correlated data, for example, near-infrared, are ideal for multivariate methods such as principal components analysis. Soft modeling, as the use of these methods is sometimes called, can relate spectra to consumer parameters. In terms of the quality of analytical results themselves, rather than the quality of a product that is determined from analytical measurements, it is not clear that multivariate methods have such a great role to play.

## Primary Standards

**R Wielgosz**, Bureau International des Poids et Mesures, Sèvres, France

### Introduction

In science and technology, the word standard is used with two different meanings:

1. a measurement standard (etalon);
2. a widely adopted written technical standard, specification, technical recommendation, or similar document.

This article is concerned with the first meaning, and it should be noted that the qualifier 'measurement' is often omitted. The International Vocabulary of Basic and General Terms in Metrology (VIM) defines a measurement standard as:

material measure, measuring instrument, reference material (RM) or measuring system intended to define, realize, conserve or reproduce a unit or one or more values of a quantity to serve as a reference.

In order to ensure the metrological properties of measurement standards a hierarchy is established between them. A primary standard is defined as

a standard that is designated or widely acknowledged as having the highest metrological qualities and whose value is accepted without reference to other standards of the same quantity.

A secondary standard is defined as

a standard whose value is assigned by comparison with a primary standard of the same quantity.

The property of standards or measurement results that allows them to be related to stated references, for example, a primary standard, through an unbroken chain of comparisons all having stated uncertainties is known as traceability. The unbroken chain of comparisons is referred to as a traceability chain (see Figure 1).

### Standards, Quantities, and Units

A measurable quantity is an attribute of a phenomenon, body, or substance that may be distinguished qualitatively and determined quantitatively. Quantities may be grouped together into categories of quantities that are mutually comparable. Lengths, diameters, distances, heights, wavelengths, and so on

would constitute such a category. Mutually comparable quantities are called 'quantities of the same kind'. If a particular example of a quantity from such a category is chosen as a reference quantity called the unit, then any other quantity from this category can be expressed in terms of this unit, as a product of this unit and a number. This number is called the numerical value of the quantity expressed in this unit.

A measurement standard is a physical realization of a quantity. The standard may represent a unit of measurement of the particular quantity, or a known value of the quantity.

**Figure 1** Primary standard of mass, the International prototype of the kilogram. The kilogram is the last remaining base unit of the SI that is still defined by a material artifact. The international prototype is kept with its six official copies in a vault at the BIPM. The international prototype was manufactured in the 1880s of an alloy of 90% platinum–10% iridium. Four of the six official copies date from the same period. In addition, copies of the international prototype have been manufactured by the Bureau International des Poids et Mesures (BIPM) for use as 1 kg national prototypes. The first of these were distributed in 1889. Since the 1880s the BIPM has produced more than eighty 1 kg prototypes in Pt/Ir. The BIPM also maintains a number of 1 kg copies for current use, one of which is illustrated in the figure. (Reproduced with the permission from International Organization for Standardization, ISO. This standard can be obtained from any ISO member and from the website, [www.iso.org](http://www.iso.org); © ISO.)

Measurement standards may be defined as primary or secondary depending on their metrological hierarchy. Additionally, they may be defined according to the role they fulfill. For example, an international measurement standard is recognized by an international agreement to serve internationally as the basis for assigning values to other standards of the quantity concerned. A national measurement standard is recognized by a national decision to serve, in a country, as the basis for assigning values to other standards of the quantity concerned. A reference standard is a measurement standard, generally having the highest metrological quality available at a given location or in a given organization, from which measurements made there are derived.

In the field of chemical measurement, certified reference materials (CRMs) and RMs are used as measurement standards. Depending on the metrological qualities of these standards, in certain fields CRMs provide a primary standard for a measurement system.

Pure substance CRMs provide the basis for many traceability chains in chemistry, and are often considered as primary standards for these measurement systems. The certification of substances for purity is an essential cornerstone of traceability in chemical measurements. These CRMs are used by laboratories to prepare calibration solutions or to certify or prepare other CRMs. The mass or amount fraction of the pure substance within the material is often determined by analyzing for possible impurities (often based on a consideration of the manufacturing process and degradation products) and the purity computed by difference.

## The International System of Units

A system of units (SI) (of measurement) is a set of base units, together with derived units, defined in accordance with given rules for a given system of quantities. The International system of units, SI, provides such a system, being the coherent system of units adopted and recommended by the General Conference on Weights and Measures (CGPM). A base unit is a unit of measurement of one of the quantities that, in a system of quantities, are conventionally accepted as functionally independent of one another. The seven base units of the SI are given in **Table 1**.

Formal definitions of all SI base units are approved by the CGPM. The first such definition was approved in 1889 and the most recent in 1983. These definitions are modified from time to time as techniques of measurement evolve and allow more accurate realizations of the base units. The definitions are

**Table 1** Base units of the SI

<i>Quantity</i>	<i>SI base unit</i>	
	<i>Name</i>	<i>Symbol</i>
Length	Meter	m
Mass	Kilogram	kg
Time	Second	s
Electric current	Ampere	A
Thermodynamic temperature	Kelvin	K

published in the SI brochure by the Bureau International des Poids et Mesures (BIPM), which also lists CGPM decisions concerning the practical realization of the definitions of some key SI units. The framework within which standards laboratories must work if units they realize are to be in conformity with those defined by the SI is also presented there. The current definitions of the SI base units are summarized in **Table 2**.

## International Metrology

The Convention of the Metre is a diplomatic treaty that gives authority to the General Conference on Weights and Measures (Conférence Générale des Poids et Mesures, CGPM), the International Committee for Weights and Measures (Comité International des Poids et Mesures, CIPM), and the International Bureau of Weights and Measures (Bureau International des Poids et Mesures, BIPM) to act in matters of world metrology, particularly concerning the demand for measurement standards of ever increasing accuracy, range, and diversity, and the need to demonstrate equivalence between national measurement standards.

The Convention was signed in Paris in 1875 by representatives of 17 nations. As well as founding the BIPM, the Metre Convention established a permanent organizational structure for member governments to act in common accord on all matters relating to units of measurement. The task of the BIPM is to ensure worldwide uniformity of measurements and their traceability to the International System of Units (SI).

The Convention, modified slightly in 1921, remains the basis of international agreement on units of measurement. There are now 51 Member States, including all the major industrialized countries.

The CIPM is advised by Consultative Committees in various areas of metrology. The Consultative Committee for Amount of Substance; Metrology in

**Table 2** Current definitions of the SI base units

Meter	The meter is the length of the path traveled by light in vacuum during a time interval of $1/299\,792\,458$ of a second
Kilogram	The kilogram is the unit of mass; it is equal to the mass of the international prototype of the kilogram
Second	The second is the duration of $9\,192\,631\,770$ periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium 133 atom
Ampere	The ampere is that constant current that, if maintained in two straight parallel conductors of infinite length, of negligible circular cross-section, and placed 1 m apart in vacuum, would produce between these conductors a force equal to $2 \times 10^{-7}$ newton per meter of length
Kelvin	The kelvin, unit of thermodynamic temperature, is the fraction $1/273.16$ of the thermodynamic temperature of the triple point of water
Mole	The mole is the amount of substance of a system that contains as many elementary entities as there are atoms in $0.012$ kilogram of carbon 12. When the mole is used, the elementary entities must be specified and may be atoms, molecules, ions, electrons, other particles, or specified groups of such particles
Candela	The candela is the luminous intensity, in a given direction, of a source that emits monochromatic radiation of frequency $540 \times 10^{12}$ hertz and that has a radiant intensity in that direction of $1/683$ watt per steradian

Chemistry (CCQM) is responsible for issues related to metrology in chemistry.

At the national level, National Metrology Institutes (NMIs) maintain measurement standards and capabilities and provide services in order to develop their national metrology infrastructures so as to underpin and facilitate the comparability of measurement results.

In October 1999, the directors of the NMIs of the industrialized states of the world signed a Mutual Recognition Arrangement (MRA) for national measurement standards and for calibration and measurement certificates issued by their institutes. This arrangement was drawn up by the International Committee of Weights and Measures (CIPM), under the authority given to it in the Metre Convention.

The objectives of the CIPM-MRA are to: establish the degree of equivalence of measurement standards maintained by NMIs; to provide for the mutual recognition of calibration and measurement certificates issued by NMIs; thereby to provide governments and other parties with a secure technical foundation for wider agreements related to international trade, commerce, and regulatory affairs. It is founded on the efforts of each individual NMI to base its measurements and measurement uncertainties on SI units.

The principal output of this MRA is a key comparison database (KCDB) at the Bureau International des Poids et Mesures ([www.bipm.org/kcdb](http://www.bipm.org/kcdb)) containing the results of international comparisons of national measurement standards and capabilities, known as key comparisons, which underpin and extensive lists of the calibration and measurement capabilities (CMCs) of NMIs. The CMCs of NMIs for chemical measurements are included in the KCDB, and listed under Amount of Substance. The chemical categories covered are: high-purity chemicals, inorganic

solutions, organic solutions, gases, water, metals and metal alloys, advanced materials, biological fluids and materials, food, fuels, sediments, soils, ores and particulates, pH and electrolytic conductivity, and other materials (see Figure 2).

### Degrees of Equivalence of Measurement Standards and Measurement Capabilities

The international comparisons of the CIPM-MRA result in a determination of the degree of equivalence of measurement standards and capabilities. The degree of equivalence of measurement standards is taken to mean the degree to which a standard is consistent with the reference value of a key comparison. The degree of equivalence of a national measurement standard is expressed quantitatively by two terms: its deviation from the reference value of a key comparison and the uncertainty of this deviation. The CCQM is active in coordinating international (key) measurement comparisons in the field of chemical measurements in the areas of organic analysis, inorganic analysis, gas analysis, electrochemical analysis, bioanalysis, and surface analysis. The results of these comparisons are publicly available and include the measurement results and their uncertainties, and a calculation of the degrees of equivalence between the measurements of the various laboratories that participate in the comparison. As an example, the graph of equivalence for a pH comparison ( $0.025 \text{ mol kg}^{-1} \text{ KH}_2\text{PO}_4 + 0.025 \text{ mol kg}^{-1} \text{ Na}_2\text{HPO}_4$  at  $15^\circ\text{C}$ ) is shown (Figure 3). The Physikalisch-Technische Bundesanstalt (PTB) piloted this comparison with the assistance of the National Institute of Standards and Technology (NIST) and the Slovak Institute for Metrology (SMU). The final

report of the comparison contains full details of the measurements, and this together with statements on how the degree of equivalences is derived is found on the KCDB, allowing the standards or measurement capabilities to be compared.

## Primary Methods

The CCQM defined a primary method as ‘a method having the highest metrological qualities, whose operation can be completely described and understood, for which a complete uncertainty statement can be

written down in terms of SI units’. A primary direct method: ‘measures the value of an unknown without reference to a standard of the same quantity’. A primary ratio method: ‘measures the value of a ratio of an unknown to a standard of the same quantity; its operation must be completely described by a measurement equation’.

A primary method provides the means to transform the abstract definition of an SI unit into practical measurements made in terms of that unit. This is sometimes referred to as a realization of that unit. The CCQM identified several methods with the potential of being primary methods of

MEASURAND: pH value of phosphate buffer  
 Sample 1:  $[0.025 \text{ mol kg}^{-1} \text{ KH}_2\text{PO}_4 + 0.025 \text{ mol kg}^{-1} \text{ Na}_2\text{HPO}_4]$   
 Measurements at 15°C

Nominal value: pH = 6.9 at 25°C

Degrees of equivalence  $D_i$  and expanded uncertainty  $U_i$  ( $k = 2$ )

measurement: isotope dilution mass spectrometry, coulometry, gravimetry, titrimetry, and determination of freezing point depression.

The CCQM is not the only international organization that has established definitions for different types of measurement methods. Others include the International Union of Pure and Applied Chemistry (IUPAC), the International Organization for Standardization's Committee on Reference Materials (ISO-REMCO), and the International Federation of Clinical Chemistry (IFCC). The definitions of absolute and definitive measurements are similar to the definition of a primary method, but neither makes reference to the use of SI units or to the traceability of the results.

## Traceability and Uncertainty

Within a robust metrological system the values of measurement standards and measurement results are linked via comparisons or calibrations that take into account the measurement uncertainty of the linking

processes. Measurement uncertainty is the parameter associated with the results of a measurement, which characterizes the dispersion of the values that could reasonably be attributed to the measurand. The ISO Guide to the Expression of Uncertainty in Measurement (GUM) and the Eurachem guide on measurement uncertainty provide guidance of the evaluation of measurement uncertainty. The property of the result of a measurement or the value of a standard whereby it can be related to stated references, usually national or international standards, through an unbroken chain of comparisons all having stated uncertainties, is termed traceability. Where these stated references are realizations of the SI units the term SI-traceable is used.

## Quantities Describing the Composition of Mixtures

Measurements in analytical chemistry are often performed on mixtures. The quantities used for expressing the composition of mixtures can be classified

into five groups: ratios, fractions, concentrations, molality, and contents. Since a number of these quantities are dimensionless the kind of quantity being measured should always be stated to avoid misinterpretation of measurement results.

## Certified Reference Materials

In the field of analytical chemistry the term certified reference material is more often used than measurement standard. A CRM is a RM, accompanied by a certificate, one or more of whose property values are certified by a procedure that establishes traceability to an accurate realization of the unit in which the property values are expressed, and for which each certified value is accompanied by an uncertainty at a stated level of confidence. All CRMs lie within the definition of 'measurement standard' previously given in this article.

The term reference material is used more generally to describe a material or substance one or more of whose property values are sufficiently homogeneous and well established to be used for the calibration of an apparatus, the assessment of a measurement method, or for the assigning of values to materials.

Some RMs and CRMs have properties that cannot be determined by exactly defined physical and chemical measurement methods. Biologicals provide an example where this is the case, where a measurement of biological activity is made relative to an internationally accepted artifact standard, to which an International unit (IU) has been assigned by the World Health Organization.

CRMs are required in many chemical analyses, in order to perform a calibration and/or validate the method being employed to ensure the accuracy, uncertainty, and traceability of the results obtained. Many modern analytical methods require the use of RMs the matrix of which is sufficiently close to the sample being analyzed to enable calibration and appropriate verification of the measurement method used.

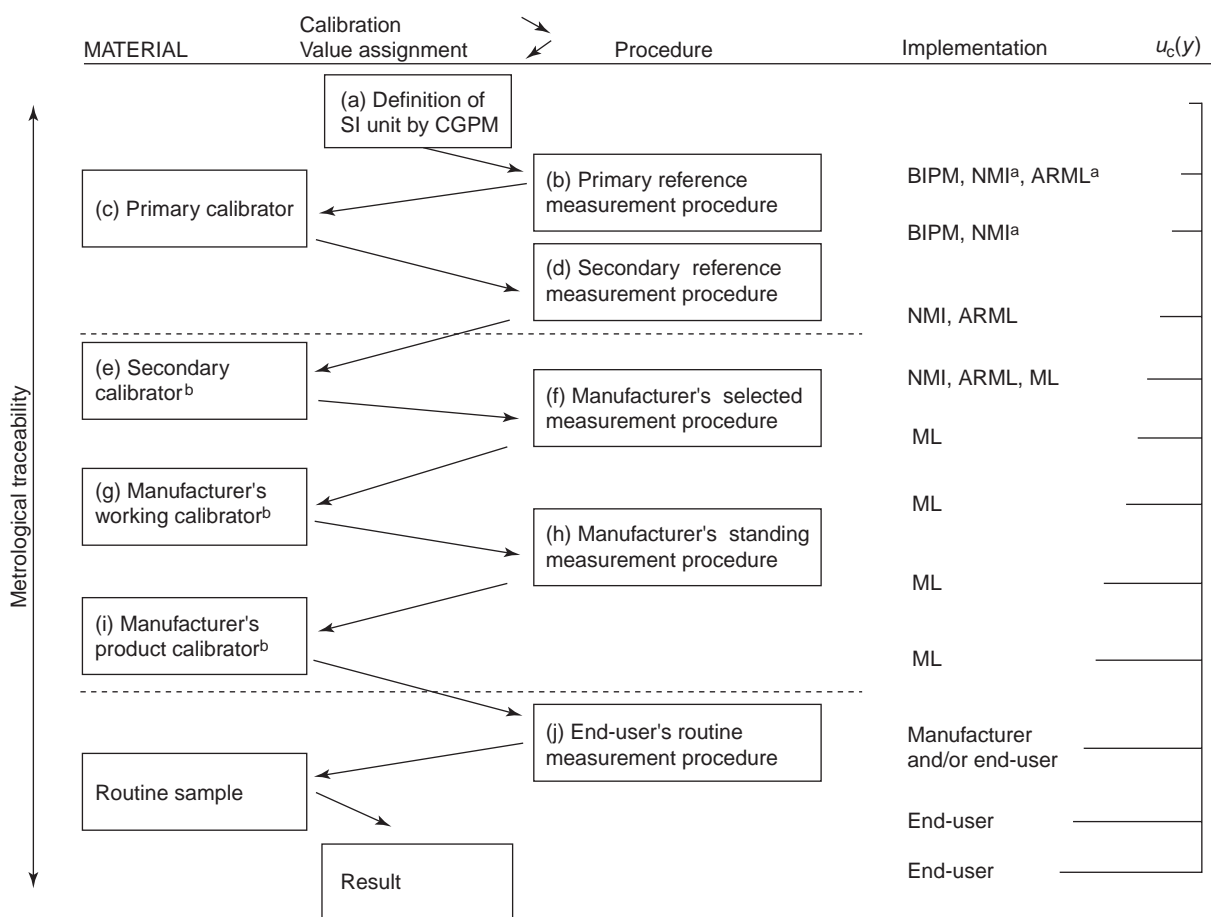

The COMAR (index Code of Reference Materials) database, initiated in the late 1970s, and now freely searchable via the internet ([www.comar.bam.de](http://www.comar.bam.de)), contains information on some 10 000 CRMs from more than 200 producers from throughout the world. The database was developed to aid chemists in finding the RMs they required. The database provides the following information on RMs: their basic area(s) of application, their certified values, their form, their country of origin, the producer, and relevant references.

The Reference Materials Committee (REMCO) of the International Organization for Standardization (ISO), formed in 1975, has been active in developing a series of guides to support best practice in the production and certification of RMs. The committee has developed two guides to assist in the establishment of facilities to produce and certify RMs and ensure their quality. ISO Guide 34 outlines the requirements to be met by a CRM producer to demonstrate competence, and ISO Guide 35 provides guidance on general and statistical principles related to the certification of reference materials, and cites models for the homogeneity testing, stability testing, and the characterization of a candidate CRM.

## Reference Measurement Systems

The concept of metrological traceability is particularly developed in a number of chemical measurement fields. In the field of laboratory medicine, ISO 17511 (*in vitro* diagnostic medical devices – Measurement of quantities in biological samples – Metrological traceability of values assigned to calibrators and control materials), describes reference measurement systems, which ensure traceability to the SI via reference measurement procedures and certified reference measurements. A calibration hierarchy with traceability to the SI is depicted in **Figure 4**. Depending on the possibility of metrological traceability to the SI, ISO 17511 envisages five typical upper ends of the metrological traceability chain:

1. Quantities for which results of measurement are metrologically traceable to SI.
2. Quantities for which results of measurements are not metrologically traceable to the SI, amongst which it is possible to differentiate:
  - a. quantities for which an international conventional reference measurement procedure and one or more conventional calibration materials with values assigned by these procedures are available;
  - b. quantities for which an international conventional reference measurement procedure is available but no conventional calibration materials are available;
  - c. quantities for which one or more conventional calibration materials with a protocol for value assignment are available, but for which there is no international conventional reference measurement procedure;
  - d. quantities for which neither reference measurement procedures nor reference materials are available.

**Figure 4** Calibration hierarchy and metrological traceability to SI (The terms and definitions taken from ISO 17511: 2003 *In vitro* diagnostic medical devices – Measurement of quantities in biological samples – Metrological traceability of values assigned to calibrators and control materials.) ### Introduction

Consider the following five observations?

Today, thanks to the genius of researchers, manufacturers, and commerce, there are more products on sale than ever before in the history of mankind. Increasing complexity is leading to a greater need for consumer protection. More and more products require testing to ensure compliance with specification and safety regulations before release to the market.

The growth in international trade, with its geographical variety of traditions, languages, standards, and habits, is adding to this need for consistency. Trade, even in simple commodities and products, demands supporting technical data, only available from analytical measurement. The achievement of the Single European Market and the GATT Agreement requires cross-frontier acceptance of test results.

The enforcement of regulation and often the administration of justice in the fields of health, safety, and environmental protection need to be based on a foundation of valid analytical measurement in which the public has confidence.

Competent calibration and traceability of measurements is essential for industrial manufacture and a major criterion in addressing product liability. It features prominently in both accreditation to ISO/IEC 17025 and certification to ISO 9001. It also underpins all testing.

The credibility of test results depends on effective method validation, which includes amongst its requirements accuracy, precision, repeatability, and reproducibility. In turn, these depend on the competence of the tester and the validity of the methods used. Those who have to accept goods must have confidence that laboratories conducting tests and calibrations are competent and that their results are valid.

In all the cases, effective quality assurance procedures can be seen as the tools that initially provide the confidence, and then maintain the compliance.

### General Requirements

Each area of science has its own specific vocabulary, and before proceeding further, it is worth considering how these definitions and principles are implemented when spectroscopic measurements are undertaken.

Often considered the primary responsibilities of the laboratory manager is the production of analytical results that are 'fit for purpose'; but again this phrase is open to interpretation.

Every result has a customer for whom the data are being generated, and addresses a specific need; e.g., to check for compliance with a specification or regulation, to monitor health, or to identify the cause of a plant malfunction. The data will be 'fit for purpose' provided it enables the customer to meet his or her needs.

Every analysis is undertaken in order to solve a problem of one type or another. The analyst needs to understand the problem and discuss it with the customer (i.e., the person requiring the data) so that an appropriate analytical procedure can be applied. It will also be necessary to take into consideration other factors that may be important to the customer. The analyst then uses all of this information to prepare a specification of the analytical requirement. The issues that need to be taken into account in preparing the specification may include:

- the nature of the samples and the way in which they were obtained;
- the information required to solve the problem;
- the criticality/acceptable risk for the analysis;
- time and cost constraints;
- bias (accuracy), precision, and degree of confidence required;
- identification or confirmation of the analyte;
- method development and validation requirements (where applicable);
- quality assurance (QA)/quality control (QC) requirements;
- regulatory or legal constraints; and
- third-party acceptance requirements (e.g., for documentation or traceability of data).

The specification should also include agreed acceptance criteria for the data. Unfortunately, disregard of the requirement to discuss and agree on the specification often results in the use of 'assumed' criteria by one or both parties. This may lead to the adoption of methodology, QA procedures, or documentation inappropriate to the purpose for which the data are required.

Increasingly, the chemical testing community is adopting QA principles, which, whilst not actually guaranteeing the quality of the data produced, increase the likelihood of it being soundly based. A quality system on its own will not, however, achieve

the desired aim unless the laboratory also adheres to 'good analytical practice'. This simple phrase embodies all the activities of the laboratory, whether technical, managerial, or quality assurance, which are needed to ensure valid results.

Good analytical practice is the basis of all the GxP ( $x = L, M$ , etc.) or cGxP standards long since mandatory in the pharmaceutical industry, and now finds an equally willing host in accreditation to ISO/IEC 17025. This new role is being driven in no small part by the conversion of ISO guide 25 in recent years to ISO/IEC standard 17025.

The International Standards Organization (ISO) clearly defines the difference between QA and QC, but these terms are sometimes mistakenly used interchangeably.

### Quality Assurance

"All those planned and systematic actions necessary to provide adequate confidence that a product or service will satisfy given requirements for quality." (ISO 8402 – 1994, 3.6)

QA describes the general quality procedures/requirements for a laboratory. These may include:

- educated, trained, and skilled staff;
- specified requirements for all chemical grades from reference material to reagent;
- suitable equipment calibrated and maintained;
- suitable laboratory environment;
- documented and validated methods;
- quality control procedures;
- check procedures for reporting and quality control;
- use of proficiency testing;
- quality system supported by a quality manager and documentation;
- a complaints procedure.

### Quality Control

"The operational techniques and activities that are used to fulfill requirements for quality." (ISO 8402 – 1994, 3.7)

Quality control procedures ensure the reliability of specific samples or batches of samples and may include routine analysis of:

- quality control samples (with results recorded on control charts);
- blanks;
- replicates (duplicate/triplicate);
- reference materials;
- 'spiked' samples;

- blind samples (i.e., samples where the laboratory staff are unaware that the result is already known).

### 'Standard' Definitions

The word standard and its use in the context of quality assurance of spectroscopic measurements can be broadly defined in three very different ways, each adding its own suffix to the term 'Standard'. These definitions can be broadly described as calibration, documentation, and reference – and such are the vagaries of the English language that these can often be subdivided further. However, each has its own vital contribution to the overall quality assurance of the spectroscopic measurements performed, and it is up to the laboratory manager to decide on the type or types required and their roles in ensuring that the data is indeed fit for purpose.

### Standard Calibration

Thanks to the Beer–Lambert law, which defines a linear relationship between absorbance ( $A$ ) and analyte concentration, the majority of analytical spectroscopic methods are quantitative in nature. These methods require the manufacture of a series of standards of increasing concentration from which a calibration function is derived, usually involving regression analysis for 'goodness of fit'.

From this method calibration, simple extrapolation of a measurement unknown will produce a concentration estimate. However, from a QA perspective, day-to-day comparisons of these simple calibration measurements, and the associated statistics, can often highlight aspects of reagent quality, apparatus (balance, volumetric glassware, etc.), and operator competence when compared. These data can be invaluable in assisting regulatory compliance, and ensuring that the complete measurement system is under control.

Whilst these standards are mostly prepared simply within the solvent matrix used, variations on this theme may result in inclusion of these standards actually within the sample matrix. These procedures are often referred to as internal standardization, standard addition, or standard recovery, depending on the actual implementation of how the known analyte addition is used within the spectrophotometric method. These procedures either provide spectral calibration or method quality assurance data. For example, spectroscopic methods will often require pretreatment to remove the interfering sample matrix. Addition of a known amount of the test analyte 'spike' (at the expected level) to a sample is

then subjected to the same pretreatment. This is then analyzed at the same time as the sample, the difference calculated, and the resultant calculated as a percentage of the original level. Clearly, anything significantly less than 100% indicates significant loss of analyte at the pretreatment stage.

### **Standard Documentation**

**Standard regulations** Briefly mentioned already, these standards all have the common requirement that, where possible, QA with traceable certified reference materials (CRMs) is required. Traceability is an essential requirement for compliance to these standards, and is fully covered elsewhere.

*Pharmaceutical 'good practices' – GxP ( $x = L, M$ , etc.) or cGxP standards* Formally introduced in the late 1970s by the FDA in the USA, these regulations were used as a basis to construct the internationally recognized Organization for Economic Cooperation and Development guidelines, issued in the early 1980s.

Broadly speaking, these standards require the submitting laboratory to provide 'evidence of control'.

*ISO 9001:2000* ISO develops and maintains the ISO 9000 series of International Standards for quality management and QA. First introduced in 1987, this series of standards has been employed by thousands of businesses worldwide and has been adopted by more than 70 countries as the national standard.

Fundamentally reviewed in 2000, this standard now places greater emphasis on customer communication and continuous improvement.

*ISO/IEC 17025:1999* Accreditation is the formal recognition of the competence of a body or an organization for a well-defined purpose. In contrast with the ISO 9001 processes, accreditation of a laboratory to ISO/IEC 17025 involves assessment of the technical competence and capability of the laboratory and its personnel. In practice, it is the procedure by which a laboratory is assessed to perform a specific range of tests or calibration measurements. Specific areas examined include infrastructure and staff qualifications, in addition to checks that an adequate quality management scheme is in place. The accreditation covers the range of materials tested or analyzed, the tests carried out, the method and equipment used, and the accuracy or precision expected, and is specific to the facility and the test.

Most national laboratory accreditation schemes have adopted this standard, which establishes the process not only as third-party audit, but an

assessment of the data generation process by a 'peer review'.

**Method** Any appropriate analytical method may be used providing it is suitable for the purpose intended, adequately validated, properly documented, and authorized by a competent person.

In many application areas, too numerous to mention, internationally recognized bodies such as ASTM International, AOAC, etc., have volumes of published standard methods. The reliability of a 'standard' method should not be taken for granted, no matter how impeccable the method's pedigree. The laboratory applying the method should satisfy itself that the degree of validation of the method is adequate for the specific purpose, and confirm that it is able to match any stated performance criteria. Validation of a method establishes, by systematic laboratory studies and/or appraisal of existing validation data, that the method is fit for purpose, i.e., its performance characteristics are appropriate to the requirements set out in the analytical specification.

### **Standard Reference**

Defined as a physical artifact, these standards may be further subdivided into the following groups.

**Reference material** ISO defines a reference material as 'a material or substance one of more of whose property values are sufficiently homogeneous and well established to be used for the calibration of an apparatus, the assessment of a measurement method, or for assigning values to materials'. In spectroscopic applications, these materials are usually substances with known, and proven spectral characteristics. They are invaluable in providing spectral data for either qualitative comparison by spectral matching or spectrophotometer qualification.

**Certified reference material** ISO defines a certified reference material as 'a reference material, accompanied by a certificate, one or more whose property values are certified by a procedure which establishes traceability to an accurate realization of the unit in which the property values are expressed, and for which each certified value is accompanied by an uncertainty at a stated level of confidence'.

These references are mandatory for regulatory compliance, and contain the essential certified value via a traceable route. Equally important from a QA perspective is a defined uncertainty budget. Given this budget figure, and the stated accuracy of the spectrophotometer (assuming the same level of confidence), simple addition of these two uncorrelated

functions will give the QA tolerance for use on the spectrophotometer of choice.

**Proficiency testing reference** Independent technical assessment of a laboratory's data provides an external benchmark, which enables the laboratory to monitor its own performance against other competent laboratories and to demonstrate its achievement of reliable results to customers. One of the best ways for an analytical laboratory to monitor its performance, both internally and externally, is to participate in proficiency testing (PT) schemes. These usually involve an organizing body that distributes an 'unknown' test sample to participating laboratories and then collates and assesses their results. Correctly used, these schemes help to highlight the success of a laboratory's quality procedures. Regular participation in PT schemes, and an associated improvement in performance, provides a means for laboratories to demonstrate their proficiency to third-party certification or accreditation organizations.

PT schemes or other types of interlaboratory comparison provides the analytical community with an alternative means to demonstrate consistency between a relatively small number of laboratories. Where the value of the test sample is independently determined these schemes also highlight systematic errors, i.e., bias. Including CRMs or results from recognized expert laboratories in a PT scheme or intercomparison is one way in which reference material producers establish certified values for new materials.

## Spectrophotometer Qualification and Calibration

The requirement that equipment should be tested and proven to be fit for purpose is effectively fulfilled by an approach known as equipment qualification (EQ), which is well established and proven in the highly regulated pharmaceutical industry. EQ is complementary to method validation for the spectrophotometer and is built on effective instrumental calibration validation (see below). EQ is a systematic procedure, which ensures that suitable equipment is purchased and that it remains fit for its chosen purpose throughout its operating life. The same requirement is present in ISO/IEC 17025, where section 5.5.5 'Records of Equipment' requires checks to ensure compliance with the specification, maintenance plans, etc.

### Calibration

Install and use any equipment in the environment of choice, and immediately the surroundings will begin

to act on that equipment causing change. Ultimately this process results in an unacceptable level of degradation in performance. This is commonly called drift, and when this happens the results become unreliable and no longer 'fit for purpose'. Whilst it may not be possible to eliminate drift, it can be detected and 'contained' using calibration. Calibration is the process of establishing how the response of a measurement process varies with respect to the parameter being measured.

CRMs are widely used to ensure both proper calibration and satisfactory use of the analytical methodology. When many laboratories use specific CRMs in a systematic way as part of QC procedures, consistency of data between those laboratories will be achieved. The main limitation in this respect is the frequent difficulty of obtaining CRMs appropriate to each type of analysis. This lack of supply is being addressed by an increasing number of secondary material producers, some of whom have already achieved ISO/IEC 17025 accreditation for production and certification of these references.

In the case of any spectrophotometric measurement, amongst the many parameters to keep in control, the three most usually measured are wavelength accuracy, linearity or absorbance accuracy, and stray light.

**Wavelength** There are several methods for checking wavelength accuracy. By far the best is to use an elemental line source. For analytical purposes, these sources can be deemed to be primary references because the line wavelengths are available as physical constants, with the wavelength determined to several orders of magnitude higher than required. For example, the principal line values in air for mercury (Hg) are established as: 253.6506, 296.7283, 312.5670, 365.0157, 404.6572, 435.8337, 546.0753, 576.9598, and 579.0663 nm (**Figure 1**). By definition, where accuracy to one or two decimal places is all that is required, these essentially become absolute wavelength calibration values. Not all instruments have the facility for fitting and using such a lamp, but recent years have seen this facility made available in top-of-the-range reference spectrophotometers. The deuterium lamp, fitted in most ultraviolet (UV) instruments, can be used in a similar manner, but it only provides two lines, at 486.00 and 656.10 nm. However, the 656.10 nm line is so intense that the second- and third-order harmonics at 1312.20 and 1968.30 nm, respectively, can be used for calibration in the near-infrared (NIR) region.

If line sources are not available, the spectra of the rare earth ions, in either liquid (as solution) or solid (as glass), can be used as useful references. In either

**Figure 1** Line spectrum produced from a mercury 'pen' lamp fitted as an alternative source in a high-performance reference commercial spectrophotometer.

**Figure 2** Absorption spectrum produced by a holmium glass certified reference material measured at the sample position in a high-performance reference commercial spectrophotometer. The singlet peak at  $\sim 360$  nm and the triplet centered at  $\sim 450$  nm are particularly characteristic of this material.

form, these elements provide characteristic spectral information right from the far-UV region (200 nm), through visible, and into the NIR ( $3\text{ }\mu\text{m}$ ) region, with the glasses exhibiting the not unexpected peak broadening associated with the matrix (Figure 2). Holmium oxide in perchloric acid solution is a favorite for the 230–660 nm region, and is available from many commercial vendors, and as a primary reference from National Institute of Standards and Technology USA (NIST) as SRM 2034 (Figure 3).

**Absorbance** There are several methods for checking either the linearity or absorbance accuracy of an instrument.

The double aperture method is a physical, not a chemical, technique that at first seems to avoid many of the disadvantages of other methods. It relies on a plate with two independently operated shutters

**Figure 3** Absorption spectrum produced by holmium oxide in perchloric acid solution, provided as a 'sealed cell' certified reference material. Measured at the sample position, in a high performance reference commercial spectrophotometer, with air as the reference.

placed at a focal portion of the light beam and so is totally wavelength neutral. The United Kingdom's National Physical Laboratory has described it as 'the most accurate, sound, simple and fool-proof technique we know for testing linearity in a manual single beam dc mode instrument'.

However, the system described requires precision optical control and alignment, only found in high-performance commercial reference spectrometers such as those employed or constructed by National Metrology Institutes (NMIs). The double aperture method, therefore, is not ideal for the routine checking of normal spectrometers.

At the far-UV end of the spectrum (200–300 nm), nicotinic acid solution in the  $0\text{--}24\text{ mg l}^{-1}$  range provides a suitable stable reference (Figure 4).

In many application areas, the use of solutions of potassium dichromate is specified for checking absorbance accuracy. The NIST supply potassium dichromate (SRM 935a) as a solid material, from which the user prepares solutions in accordance with NIST Special Publication 260-54 (Figure 5). This process, as does any similar preparative procedure, therefore, relies on the laboratory chemist making up the solutions correctly, and is as much a test of his or her competence as it is of the instrument's performance. 'Preparative' used in this context can simply refer to the act of decanting a supplied bottled or ampouled solution into the measurement cuvette. This method can be extremely useful if one wishes to establish the total competence of a laboratory, but not so if the aim is to establish the calibration of the spectrophotometer only. If results are obtained that appear to question the accuracy of the spectrophotometer, is the instrument or the accuracy of the solution in question? To offer a remedy to this conundrum a few reference material producers now

**Figure 4** Absorption spectra produced by a series of acidic nicotinic acid solutions, provided as 'sealed cell' certified reference materials. Measured relative to a solvent blank, at the sample position, in a high-performance reference commercial spectrophotometer.

**Figure 5** Absorption spectra produced by a series of acidic potassium dichromate solutions, provided as 'sealed cell' certified reference materials. Measured relative to a solvent blank, at the sample position, in a high-performance reference commercial spectrophotometer.

offer sealed cells of potassium dichromate solution, prepared in perchloric acid to improve the stability, and under clean room conditions to minimize contamination.

Neutral density filters made of gray glass have been in use for over 30 years as absorbance reference materials and have shown themselves to be extremely stable and ideal for use in the visible portion of the spectrum, where they are now employed as the definitive reference. However, interest is now being expressed in extending the use of these glasses into both the NIR and mid-IR regions. They are available from NIST (as SRM 930, 1930, and 2030) or as secondary CRMs from a number of manufacturers. Care must be taken in mounting the filters, in manufacturing them to exacting standards, particularly with respect to parallelism of the optical faces, and in certifying

their absorbance values. The main disadvantage of these filters is that they cannot be used in the UV.

Metal on quartz filters have been proposed in recent years as an alternative method for checking absorbance accuracy. They are usable over a wide wavelength range, and have good thermal stability. However, their optical homogeneity is poor (1 in 100 instead of the required 1 in 1000), and their major disadvantage is that they work by reflecting light rather than by absorbing it. Reflected light can hit other optical surfaces and in turn be reflected back by them. Significant interreflection errors can occur. In fact, a major use of these filters is to check for such errors.

**Stray light** Stray light is one of the most difficult of the parameters to check. It is extremely wavelength and sample dependent, so any checks must be qualified. In a modern instrument employing master holographic gratings and coated optics, stray light is usually not an issue when the instrument is first manufactured. However, as the spectrophotometer optics and/or sources age and degrade, the instrumental stray light will increase with time. It is for this reason that from a QA perspective the often-neglected stray light check will give an overall 'health check' on the performance of the spectrophotometer.

Most instrument manufacturers rely on the tests specified by ASTM International (standard E387), involving solutions with sharp cutoffs to measure stray light.

If the UV stray light has deteriorated, a useful check is to look at the number of hours the deuterium lamp has been in use. Today's better instruments include a 'lamp hours' feature as part of their software. The output of the deuterium lamp decays with age, and although the actual amount of stray light will be fairly constant with time, the relative amount increases as the lamp energy falls.

## Customer Requirements

In a modern laboratory, even simple QA procedures are an integral part of providing spectroscopic data that are 'fit for purpose'.

A considered assessment of just what is required to ensure both the quality of the data produced and more importantly the acceptance of the 'customer' is paramount to the whole QA concept. Procedures must be matched to requirements to ensure that whilst sufficient checks and controls are put in place, these are not perceived as excessive or overbearing. For example, in a manufacturing environment, a simple spectroscopic comparison reference measurement

**Figure 6** Quality assurance control chart of an absorbance scale certified reference material, measured regularly on a high-performance reference commercial spectrophotometer. The dotted trace indicates a moving average calculation on the data, showing a possible seasonal trend in the performance of the spectrophotometer.

of an unknown, against a known reference, may be all that a client will require as proof of compliance. However, if the same product is to be sold into a regulated environment, use of a CRM with full traceability is an essential requirement.

Therefore, effective combination and use of one or more of these 'standards', as appropriate, will provide the data for effective QA of modern spectroscopic methods.

One QA tool, which is yet to be mentioned, is the use of control charts. Having generated the spectroscopic data, their benefit as an immediate visual indication as to the control state of a process or procedure cannot be overstated.

Apart from displaying the obvious out-of-control conditions, trend analysis of the data will often reveal subtle changes in the instrument, not revealed on a day-to-day basis. For example, long-term drift

or seasonal variation may be observed. The example shown is one such case (Figure 6).

Increasing use of fluorescence, micro-plate readers, and fiber-optic based systems all pose their own individual QA requirements and problems, and these are only just now beginning to be addressed.

## Introduction

This article considers the role of internal standards in the quality control of quantitative assays of organic compounds. An internal standard can be defined as a second compound, not the analyte, which is added at some stage in an assay with the intention of

correcting for systematic errors. The use of internal standards in analytical procedures such as chromatographic analyses was once considered mandatory by some. Indeed, assays utilizing internal standards were once assumed to be superior to those without, even when there was little or no supporting evidence. In the 1970s, these views were beginning to be questioned, and articles began to appear that demonstrated that the indiscriminate use of internal standards was much more likely to reduce the quality of an assay than to improve it. Moreover, with the

**Figure 6** Quality assurance control chart of an absorbance scale certified reference material, measured regularly on a high-performance reference commercial spectrophotometer. The dotted trace indicates a moving average calculation on the data, showing a possible seasonal trend in the performance of the spectrophotometer.

of an unknown, against a known reference, may be all that a client will require as proof of compliance. However, if the same product is to be sold into a regulated environment, use of a CRM with full traceability is an essential requirement.

Therefore, effective combination and use of one or more of these 'standards', as appropriate, will provide the data for effective QA of modern spectroscopic methods.

One QA tool, which is yet to be mentioned, is the use of control charts. Having generated the spectroscopic data, their benefit as an immediate visual indication as to the control state of a process or procedure cannot be overstated.

Apart from displaying the obvious out-of-control conditions, trend analysis of the data will often reveal subtle changes in the instrument, not revealed on a day-to-day basis. For example, long-term drift

or seasonal variation may be observed. The example shown is one such case (Figure 6).

Increasing use of fluorescence, micro-plate readers, and fiber-optic based systems all pose their own individual QA requirements and problems, and these are only just now beginning to be addressed.

## Introduction

This article considers the role of internal standards in the quality control of quantitative assays of organic compounds. An internal standard can be defined as a second compound, not the analyte, which is added at some stage in an assay with the intention of

correcting for systematic errors. The use of internal standards in analytical procedures such as chromatographic analyses was once considered mandatory by some. Indeed, assays utilizing internal standards were once assumed to be superior to those without, even when there was little or no supporting evidence. In the 1970s, these views were beginning to be questioned, and articles began to appear that demonstrated that the indiscriminate use of internal standards was much more likely to reduce the quality of an assay than to improve it. Moreover, with the

increased use of reproducible injection systems, stable detection systems and extraction methods that gave reproducibly high recoveries, such as solid-phase extraction, the days when internal standards were routinely necessary appeared to be numbered. That was until the introduction of liquid chromatography (LC)–tandem mass spectrometry (MS–MS) when the need for suitable, and carefully chosen, internal standards became apparent. This article considers the arguments for the use of internal standards and illustrates some of the problems that can arise and how they may be minimized.

A constant amount of internal standard must be added with a high degree of precision to each sample. Accuracy is generally less important, and within limits, an internal standard does not need to be as pure as the analyte. Depending on the reasons for its inclusion, the internal standard, may be added at the beginning or at later stages in the assay procedure.

Before using an internal standard, the following should be considered:

1. Internal standards are useful for correcting systematic errors that occur in some assays, but the need for one should be identified before spending time and effort on finding one.
2. One should be prepared to spend at least as much time and effort on validating the use of the internal standard as that given for the analyte. Since using an internal standard frequently increases the analysis time, it is worth ensuring that the choice is the right one.
3. It should be demonstrated that the internal standard is performing as required and that its inclusion confers an overall benefit.
4. It may be necessary to develop the method without the internal standard if it fails to meet the requirements.

### Requirements of an Internal Standard

In 1981, Haefelinger listed his criteria for an internal standard, which, summarized, were as follows.

It must

1. be completely resolved from the known and unknown substances in the chromatogram;
2. be eluted near the peak of interest;
3. have a similar peak height (or area) to the substance to be determined;
4. be chemically similar to the substance of interest;
5. be chemically stable.

For the analysis of drugs in biological materials:

1. the internal standard should be added to biological samples in solution (preferably aqueous) and the samples thoroughly mixed to ensure uniform distribution of the internal standard;
2. where there are extraction steps, 'the internal standard should show similar behavior to the analyte; namely, the partition coefficients should be equal';
3. the internal standard should not be a metabolite of the drug of interest (nor a decomposition product or other drug that may be present);
4. it should not interfere with the metabolites of the drug or endogenous compounds.

To evaluate the validity of this list it is helpful to consider the rationale for the use of internal standards and to consider the types available.

### Reasons for Use

**Reproducibility of injection** Manual injection of small volumes of analyte solution on to gas chromatographic columns is not very precise. Provided that the detector response to the internal standard is linear, the signal given by the internal standard should be directly proportional to the volume of sample injected. Thus, if all the samples contain the same concentration of internal standard a calibration curve of:

$$\frac{\text{analyte response}}{\text{internal standard response}}$$

versus analyte concentration can be constructed. If unknown samples are treated in the same way, response ratios can be used to derive the analyte concentration – compensation for differences in injection volume having been made. The same reasoning applies to situations where a volatile injection solvent is used. In this case, the drug and internal standard concentrations will rise as the solvent evaporates, the response given by the internal standard being inversely proportional to the volume of solution remaining.

**Instability of the detection system** Some detection systems are prone to instability. Contamination of electron capture, nitrogen–phosphorus (NPD), and electrochemical detectors may lead to gradual or even sudden loss of sensitivity. A suitably chosen internal standard may compensate for such changes. However, the analyte–internal standard signal ratio must remain constant for a given mixture. If detector contamination results in nonlinear changes and different compounds are affected to differing degrees, the use of an internal standard is fallacious.

**Pipetting errors and evaporation of extraction solvent** Once an internal standard has been added, losses on sample transfer, e.g., taking less than the total amount of extraction solvent, should be reflected in its recovery. It can be argued, therefore, that inclusion of an internal standard obviates the need for quantitative transfer and so cheaper glassware, e.g., Pasteur pipettes, or quicker methods, such as pouring, may be used to separate the phases. If the transfer volumes are measured, good precision can be obtained without an internal standard. Moreover, measuring the volumes of the phases transferred is to be recommended as the internal standard response should be relatively constant and any deviation should alert the analyst to a problem. Evaporation of solvent (e.g., diethyl ether) during handling and changes in phase volumes will give errors (usually an overestimate of the analyte concentration) that can be reduced by inclusion of an internal standard.

**Extraction efficiency** For an internal standard to compensate for extraction efficiency it must be as chemically similar to the analyte as possible. Thus, isotopically labeled internal standards should be the most appropriate or if these are unsuitable, or unavailable, then the closest suitable homolog should be selected. A problem arises when several compounds, e.g., a drug and its metabolites, are to be quantified, as the extraction characteristics of each will be different. Some studies may require more than one internal standard. If the extraction efficiency is high, <95%, then inclusion of an internal standard may give only marginal improvement. The same is true of situations where the extraction efficiency is lower but reproducible.

**Derivatization and nonstoichiometric reactions** Ideally, only isotopic internal standards should be used, as it is naive to expect two chemically distinct entities to react identically. The causes of the imprecision should be investigated and the reaction conditions modified to make them suitably robust rather than rely on the inclusion of a second compound. However, potential problems with isotope internal standards need to be considered, particularly if the bond(s) linking the isotope to the rest of the molecule are involved in the reaction. It may be necessary use alternative sites of labeling.

**Protein binding, precipitation, and adsorption** The inclusion of internal standards to correct for differences in protein binding, losses on protein precipitation, and adsorptive losses is far from ideal unless the compound is as chemically similar as possible to the analyte, preferably an isotopically labeled internal

standard. When recovery is very variable, radio-labeled analyte, added as a tracer, can prove effective. Conversely, when the analyte is radioactive, the use of 'cold' analyte, as an internal standard and carrier, is valid and to be recommended. Normally, it should be possible to add sufficient carrier to use a relatively simple assay – e.g., liquid extraction and ultraviolet detection prior to radioactive counting.

### **Types of Internal Standard**

Internal standards can be considered under four major groups: isotope, homolog, generic, and chemically unrelated. To some extent the type of internal standard dictates its applicability.

**Isotope** Because isotopically labeled materials are as chemically close to the analyte as possible without being identical to it, these should be the most satisfactory internal standards, fulfilling the majority of requirements. However, difficulties arise. First, suitably labeled materials have to be available or synthesized and, second, they have to be quantified. When using radiolabeled internal standards, the sample normally has to be divided for the radioactivity to be counted. Molecules containing stable isotopes are usually quantified by MS. Furthermore, there is increasing evidence that isotopic effects are more common than was once thought and assumptions of identical chemical properties cannot be made.

The nuclides suitable for incorporating in drugs and related biological materials include the stable isotopes deuterium ( $^2\text{H}$ ),  $^{13}\text{C}$ ,  $^{15}\text{N}$ , and  $^{18}\text{O}$ , and the unstable isotopes  $^3\text{H}$ ,  $^{14}\text{C}$ ,  $^{32}\text{P}$ , and  $^{35}\text{S}$ . Generally, synthesis of high specific activity radiolabeled drugs is beyond the scope of most analysts, so if the material is not commercially available it will have to be custom-synthesized. High-purity  $^2\text{H}$ -labeled reagents, e.g., acetic anhydride, iodomethane, and lithium aluminum anhydride, are available at reasonable cost so that preparation of a stable internal standard is possible provided that a suitable precursor is available. Sometimes the precursor can be derived from the drug either chemically or metabolically, e.g., a tertiary amine may be desalkylated and then reacted with the appropriate labeled iodoalkane to give the internal standard. Alternatively, an already labeled compound may be modified, e.g., [ $^2\text{H}$ -N-methyl]-7-hydroxychlorpromazine has been isolated from the feces of rats dosed with [ $^2\text{H}$ -N-methyl]-chlorpromazine.

Trace amounts of radioactive internal standards are used so that their contribution to the 'cold' assay

is negligible. Thus, for low-level assays high specific activity material will be required and there is potential for decomposition. For mass spectral analysis the internal standard is usually added at a higher concentration than the analyte, e.g., 100-fold. This results in the assay being conducted over a narrower 'total' concentration range, thus minimizing concentration-related effects such as adsorption. The isotopic purity of the material will limit the amount that can be added for a particular limit of quantification. As the amount of nonlabeled material in the internal standard is constant, a calibration curve with a significant positive intercept is permissible providing the blank and lowest calibration standard can be distinguished.

It cannot be assumed that labeled and nonlabeled compounds are chemically identical. They are not. Bonds linking heavier isotopes are more stable and if such a bond is broken, in a chemical reaction or due to decomposition during the assay, then the heavier isotopic material will react at a slower rate and the ratio of labeled to nonlabeled compound will change. These effects are most noticeable with the isotopes of hydrogen as the mass differences are two- and three-fold. Labeled material may show chromatographic differences and integration parameters may need to be adjusted to compensate for differences in retention times. Deuterium labeled internal standards elute slightly earlier from gas chromatography (GC) columns. The partial resolution of a deuterated internal standard by liquid chromatography (LC) was reported as early 1976 (Figure 1). The larger the number of deuterated atoms the higher the degree of resolution. Baseline resolution of analyte and internal standard allows alternative forms of detection, such as fluorescence (Figure 2). Such observations of differences in chromatographic behavior must cast doubt on assumptions about the chemical similarity of labeled and nonlabeled materials, particularly with regard to solvent partitioning and solid-phase extraction.

**Homolog (analog) internal standards** Isotopic internal standards are not routinely used as the increased costs, both for the materials and the instrumentation, do not justify it and homolog internal standards can provide a reasonable alternative. Often the chemical similarities between a compound and its closest homolog are such that this approach gives satisfactory results. If needs be, higher homologs can be used but this is may not be so successful. It should be noted the addition of even one methylene group can have a marked effect on the extraction efficiency and this should be

**Figure 1** Partial resolution of the mianserin analog, Org GC 94, and its tetradeuterated internal standard (Org GC 94- $d_4$ ) by LC. invested to ensure that the extraction conditions are optimum for both the analyte and the internal standard.

**Generic internal standards** This term is used to describe compounds, which are not homologs, but are chemically similar to the analyte, for example, compounds substituted with different halogen atoms, or containing an additional group. The chemical properties of compounds in this group would not be as similar as those expected of homologs but within certain constraints these compounds may prove to be useful internal standards. Care should be taken if they are used to compensate for extraction efficiency or derivatization reactions and, of course, the internal standard must not be a putative metabolite or decomposition product. These types of internal standards, however, are suitable for compensating for differences in injection volumes and changes in detector sensitivities.

**Unrelated compounds** These should be reserved for compensating for differences in injection volumes and transfer volumes only. They are sometimes chosen because alternatives are not available: their position on the chromatograph being the primary criterion for the choice.

## Choice and Supply

Suitable internal standards may be readily available from chemical suppliers, colleagues in organic chemistry departments, pharmaceutical companies, etc. If they are not, the possibility of having them synthesized or preparing them in the analytical laboratory should be considered. This is generally preferable 'to making do' with a less suitable compound. Preparation of internal standards should not be daunting. An internal standard need not be 100% pure and relatively small quantities will often suffice. At least, to prove the validity of using the chosen compound as an internal standard, prior to having a larger batch synthesized, should that proof be necessary. The reaction can be monitored using the analytical tools that are to be employed in the proposed analysis and, for sensitive assays, it is often possible to isolate sufficient product by thin-layer or liquid chromatography.

Often the chemistry required to synthesize an internal standard is not dissimilar to the derivatization reactions with which the analysis will be familiar. **Figure 3** shows examples of the types of reactions that have been used to prepare internal standards in an analytical laboratory. Whenever possible the closest homolog (or analog) should be prepared. The paracetamol homolog was produced by shaking 4-aminophenol hydrochloride with propionic acid anhydride in water until the product

precipitated (~30 min). The filtered solid was pure enough for use without further treatment. Crystallization from ethyl acetate conferred no additional benefit.

Tertiary and secondary amines are often metabolized by desalkylation and these metabolites may be available as reference compounds. This was the approach adopted for morphine internal standards. *N*-Desmethylnormorphine (normorphine) was used as the starting point for preparation of the *N*-ethyl and *N*-propyl homologs. The secondary amine was treated with the appropriate iodoalkane and the products separated by thin-layer chromatography. The example in **Figure 3** shows the synthesis of [<sup>2</sup>H-methyl]-trifluoperazine, the secondary amine precursor having been synthesized from readily available starting materials. Quaternary ammonium by-products present little problem as they do not extract into organic solvents and tend to remain at the origin of thin-layer plates. If the desalkyl material is not available and is difficult to synthesize then it may be possible to dealkylate the analyte. This approach was used for the alkaloid hyoscyne (scopolamine), as the cost of total synthesis would have been prohibitive. The desmethyl compound was obtained by permanganate oxidation and used to give a number of potential internal standards including: the *N*-ethyl, *N*-propyl homologs and deuterium and tritium labeled [*N*-methyl]-hyoscyne.

For more complex structures, a metabolite or decomposition product may provide the best approach. Esters may be hydrolyzed and the product reesterified to give the required product. Physostigmine (**Figure 3**) was hydrolyzed with sodium hydroxide under nitrogen to give the phenol, eseroline, which on treatment with *N,N*-dimethylcarbamoyl chloride gave the *N,N*-dimethylcarbamate analog. Ethyl and propyl homologs were prepared by treating the eseroline with ethyl or propyl isocyanate in the presence of a trace of sodium, but, after evaluation, these were rejected as internal standards.

Reference materials and internal standards may be obtained by simple oxidation or reduction reactions. Reduction of *O*-ethylmorphine gave the *O*-ethyl homolog of dihydrocodeine. The 7,8-hydrogenation was accomplished by bubbling hydrogen into an acidic solution of the compound in the presence of a little Pt catalyst on barium sulfate (**Figure 3**). The reaction was monitored by LC. When a similar approach was adopted to produce an internal standard for dihydromorphine, the hydrogenation of nalorphine proceeded in two stages (**Figure 3**), which were easily monitored by LC (**Figure 4**). The final product (checked by nuclear magnetic resonance) was *N*-propyl-7,8-dihydronormorphine.

**Figure 3** Examples of internal standards prepared in an analytical laboratory.

If simple chemical reactions are inappropriate then metabolism or decomposition may be alternative approaches. Isotope-labeled materials lend themselves to this approach. The labeled precursor can be incubated with enzymes or extracted from excretion products after administration to animals. The recovery of material is easier when the material is radioactive, but the technique can be applied equally well to nonradioactive material. Small quantities of otherwise expensive isotopic material can be obtained this way; for example, deuterium labeled 7-hydroxychlorpromazine (for GC-MS analysis) has been

extracted from the feces of rats dosed with labeled chlorpromazine.

#### Will an Internal Standard Improve the Assay?

That an internal standard is 'just something else to measure and something else to go wrong' may be an extreme view, but also it should not be assumed that its inclusion will inevitably improve the precision and accuracy of a chromatographic method. The use of an internal standard should not be expected to reduce the imprecision of an assay caused by random

**Figure 4** Use of HPLC to monitor the preparation of an internal standard. The chromatograms show the two stage reduction of nalorphine (A) to 7,8-dihydronalorphine (B) and subsequent reduction of the allyl group to give the *N*-propyl-7,8-dihydro product (C).

errors. Indeed, the random errors associated with the quantification of the internal standard are likely to 'increase' the overall imprecision rather than reduce it. From replicate assays of analyte and internal standard, mean responses (e.g., peak height or area) and their associated relative standard deviations  $RSD_a$  and  $RSD_{is}$  can be obtained. The relationship between the deviations in the measurement of the responses of the individual compounds and the ratio as used in a typical assay is given by:

$$(RSD_r)^2 \approx (RSD_a)^2 + (RSD_{is})^2 - 2r(RSD_a) \cdot (RSD_{is}) \quad [1]$$

where  $r$  is the correlation coefficient between the responses to the analyte and internal standard. If the precision of the assay has been improved by the introduction of the internal standard then:

$$RSD_r < RSD_a \quad [2]$$

Substituting eqn [1] in eqn [2] and rearranging gives:

$$RSD_{is} < 2r \cdot RSD_a \quad [3]$$

Thus, depending on the correlation between the responses to analyte and internal standard and imprecision associated with those responses, inclusion of an internal standard may reduce or increase the overall imprecision. Even when  $r = 1$ , the RSD for the internal standard must be less than half that of the analyte, for an overall improvement in the assay. If the compound under test can be determined with high precision in the absence of internal standard, then the above equation confirms what one would instinctively feel should be the case, namely that

**Figure 5** Amount injected-response curves for an imaginary analyte (A) and internal standard (IS).

addition of an internal standard will not improve the situation, but rather, if anything, worsen it. A large RSD for the internal standard would indicate that the compound was a poor choice. To test the effect of the internal standard on assay accuracy and precision, calculate them using the analyte response data.

A crucial assumption that is generally made is that the response to the internal standard is linear. What is not so often considered is the effect that an intercept can have. **Figure 5** shows two 'perfect' amount injected-response curves. The line representing the response to the internal standard:

$$\text{response} = -0.5 + 2 \times (\text{amount injected}) \quad [4]$$

has a small negative intercept. A reasonable choice for the working amount of the internal standard would be 5 – this is in the middle of the linear range. If the internal standard is to perform as it should, then for a given ratio of amount of analyte to internal standard the response ratio should be constant, no matter what volume of solution is injected. Assume there is 1 mass unit per microliter of solution, thus injecting 5  $\mu\text{l}$  will give an internal standard response of 9.5. If half the volume were injected, the response would not be  $9.5/2 = 4.75$ , but 4.5 (from eqn [4]). This would result in the analyte amount being overestimated by 5.5%. If only 1  $\mu\text{l}$  were injected the corresponding overestimate would be 26.7%. This is a rather extreme example to illustrate the potential problem that can arise if the internal standard concentration-response curve does not pass through a 0,0-origin. One would expect such a problem to be identified during method development and validation.

However, when methods are modified, e.g., when seeking more sensitivity, the amount of internal standard may be reduced and the fact that there is an intercept may become significant. The concentration–response curve for the analyte need not be linear but clearly, if the internal standard curve is not linear then the results using:

$$\text{analyte response/internal standard response}$$

will be bizarre.

**Practical examples of use** An internal standard should be introduced when it is thought that the effects of a systematic error can be reduced by its inclusion. The potential usefulness of an internal standard can be tested by deliberately perturbing the system at the point where the error is thought to occur. For example, if accuracy of injection volume is suspect, then differing volumes of a test mixture of analyte(s) and internal standard should be injected to demonstrate that the analyte–internal standard ratio remains constant. The use of 1-propanol as an internal standard for ethanol determined by gas–liquid chromatography is typical of their use to correct for variability in injection volume (Table 1). Using peak height ratio, rather than peak height, generally gave smaller intraassay coefficients of variation and the correlation coefficient of the calibration graph increased from 0.9899 to 0.9993 when peak height ratios were used. If the pH of the extraction is thought to be critical, this should be tested by performing the extraction at pH values either side of the optimum. Figure 6 shows the pH–extraction curves for morphine and its *N*-ethyl and *N*-propyl homologs. The extraction characteristics of the ethyl homolog were very similar to those of morphine, but those of the propyl homolog were not so close. Furthermore, the ethyl homolog chromatographed with a suitable retention time whereas the propyl compound chromatographed close to the void volume of the column. Consequently, the ethyl compound was chosen. The extraction characteristics of dextromethorphan (Figure 5), which has been used as the internal standard in previous morphine assays, illustrate that this compound is far from being an ideal candidate. Comparison of the intraassay RSDs showed that inclusion of *N*-ethylnormorphine improved the precision of the assay at the three concentrations (100, 50, 10 ng ml<sup>-1</sup>) tested. The RSDs were 3.6, 5.1, and 6.0%, respectively, without internal standard and 0.6, 1.2, and 3.5% with the internal standard.

If detector stability is the problem it may be possible to study the effect of changing the conditions.

**Table 1** Comparison of intraassay precision of ethanol assay with and without 1-propanol as internal standard

Concentration (mg dl <sup>-1</sup> )	RSD (%)	
	Peak height evaluation	Peak ratio evaluation
25	4.40	3.79
50	10.24	8.75
100	5.47	5.42
150	9.48	3.44
200	4.45	4.95

**Figure 6** Comparison of the extraction characteristics of an analyte (morphine, ●) and its first homologs (*N*-ethyl, ○, and *N*-propyl, △). The extraction of dextromethorphan (□), used as internal standard in a published method, is shown for comparison. The extraction solution was 10 volumes butanol + toluene (1 + 9) to one volume of aqueous buffer.

In the example above, changes in electrochemical detector responses to morphine as function of applied voltage were paralleled by the responses to the ethyl homolog. The peak height ratio remained between 0.56 and 0.57 for a test mixture injected at applied potentials ranging from 0.6 to 1.0 V versus Ag/AgCl. Similarly, this approach was used successfully in the GC–NPD determination of fluphenazine. Repeated injections of trimethylsilyl fluphenazine resulted in a progressive decrease in detector response; however, addition of thioridazine to the injection solution compensated for this loss of sensitivity. The peak height ratio of fluphenazine–thioridazine for test solutions was shown to vary by <2% even when the peak height response to fluphenazine had declined by as much as 80%. The detector sensitivity was restored by periodically increasing the temperature of the rubidium silicate bead for a few minutes. This is an example of a ‘generic’ internal standard chosen on the basis of (1) the way detector responses to it parallel changes in analyte response when the detector conditions (hydrogen flow and bead temperature) were varied and (2) its position in the chromatogram.

It should not be assumed that because a compound was a suitable internal standard for a particular assay

**Table 2** Physostigmine–internal standard ratio in 0.1 ml fractions collected from five solid-phase extraction columns

Fraction (ml)	Diol	C-18	C-8	C-2	CN
0–0.1	0.8	1.8	1.2	1.3	2.3
0.1–0.2	1.0	0.8	0.8	0.8	0.8
0.2–0.3	1.5	0.3	0.8	0.6	1.0

that it will still be suitable if the method is changed. This is exemplified by the observations with physostigmine and its *N,N*-dimethyl analog, which had been shown to be a useful internal standard for liquid–liquid extraction. When a solid-phase method was developed it became apparent that the internal standard was no longer making a useful contribution. The ratio of drug to internal standard eluting from solid-phase columns is shown in **Table 2**. The peak height response ratios for three fractions from five types of column show that the analyte and internal standard are partially resolved. On the C-18, C-8, and C-2 columns the drug eluted first, whereas on the diol column the more lipophilic internal standard eluted first. With the nitrile column the internal standard eluted as a sharper peak. In no case did the ratio remain constant for the fractions. Fortunately, the precision of the solid-phase extraction was shown to be acceptable without an internal standard and so the method was developed without one.

**Internal standards for GC–MS and LC–MS–MS** Because of variations in the degree of ionization, the use of internal standards is vital when using MS for quantitative detection. Tandem MS – selecting the parent ion and a subsequent daughter ion – held the promise of specific and sensitive analyses with little or no sample preparation. However, because of interferences from the sample matrix, some form of chromatographic ‘cleanup’ is required. LC–MS–MS methods often use short chromatographic columns, relying on the mass spectrographic resolution of specific ions rather than chromatographic separations to impart the required selectivity; the advantage of this approach being short cycle times and high sample throughput. However, one ignores the coeluting but ‘unseen’ materials from the sample matrix at one’s peril. The most common phenomenon is a reduction of signal due to endogenous materials in the sample competing with the analyte during the ionization process. Ion suppression is frequently observed with electrospray interfaces and is largely unpredictable and variable. Clearly, this is a case for the use of isotopically labeled internal standards and it has been shown that this approach can be successful – although ion suppression may reduce the signal to the

extent that sensitivity is compromised. In some instances, for example, during drug development, isotopically labeled internal standard may not be available and a second compound may have to be used. Generally such a compound will be fully or partially resolved chromatographically and there is every possibility that the degree of ion suppression will be different. Increased, and uncompensated, ion suppression of the internal standard will lead to an overestimate of the analyte. That labeled and unlabeled compounds may partially resolve during chromatography must be borne in mind not only with regard to choosing the correct integration parameters, but also that the degrees of ion suppression may be different.

Any isotopically labeled material must be chosen such that bonds linking them are not broken during fragmentation as bonds bearing heavier isotopes are more stable and the resulting fragmentation pattern will differ from that of the analyte.

#### Working without an Internal Standard

When a suitable internal standard cannot be identified, it will be necessary to work without one. This does not mean that the method will inevitably suffer from poor precision and accuracy; however, several points will have to be observed:

1. Keep the number of steps to a minimum; for example, consider injecting the sample directly or after dilution, increasing the detector sensitivity or selectivity if necessary to accommodate this.
2. If ‘cleanup’ and concentration steps are required, consider solid-phase extraction as this often gives high recoveries with low standard deviations.
3. When liquid–liquid extraction is used the transfer volumes must be measured to ensure consistency across all samples. Volatile extraction solvents are best avoided as it is difficult to assess the volume change during handling. When feasible, concentration of the sample by back-extraction into a small volume of liquid is preferable to evaporation.
4. Completely (over) fill the sample loop when injecting on to LC columns to ensure minimum error. Similarly inject as large a volume as possible on to GC columns to reduce the errors associated with small volumes. Use of the ‘solvent-flush’ technique may be beneficial. A small volume of solvent is drawn into the syringe, then air until the meniscus can be seen; the sample is loaded using the movement of the meniscus to measure the volume and finally more air is withdrawn until the ‘slug’ of sample can be seen. The volume of sample, seen between the menisci, can be checked before injection. This approach had the added advantage that it reduces carryover between samples.

## Introduction

The analytical chemical picture of a studied object is provided by a measuring instrument. The results of analytical measurements are required by a wide range of users, and thus standardization approaches must be employed to assure their accuracy, precision, and low uncertainty in their interpretation.

Any measuring equipment fulfills two tasks:

- It converts the analyte amount into an electrically measurable quantity, which is termed the signal
- It treats the signal electronically and using computing techniques.

The creation of the signal is connected with a physical, chemical, or biological interaction of the analyte within the part of the measuring instrument called the sensor, followed by conversion into a measurable electrical quantity. This section of the measuring instrument is called the transducer. The subsequent algorithmic treatment of the signal provides rough data that are further refined. The measuring procedure can be depicted as shown in **Figure 1**, from which the analyte amount/signal

conversion factor is obtained, which involves all the principal properties of the measuring system.

The analyte amount/signal conversion factor is termed the sensitivity. It follows from the scheme in **Figure 1** that the conversion factor involves many unknown parameters that are specific to the particular measuring instrument and that the sensitivity has no general significance but that it is specific for a given analytical application. The set of properties of the conversion factor is termed the characteristics of the measuring system. Two models have been formulated for determination of the measuring systems characteristics, namely, the signal model and the response model.

## Signal Model

The signal model expresses the relationship between the analyte signal ( $S_i$ ) and the analyte amount ( $m_i$ ). The sensitivity of the measuring instrument is expressed in terms of the product of the construction properties of the measuring instrument ( $k$ ) and a quantified physical, chemical, or biological property of the analyte ( $a_i$ ) that can be used for the measurement. It holds that

$$S_i = (k * a_i) * m_i^l \quad [1]$$

where  $l$  is the linearity coefficient.

## Introduction

The analytical chemical picture of a studied object is provided by a measuring instrument. The results of analytical measurements are required by a wide range of users, and thus standardization approaches must be employed to assure their accuracy, precision, and low uncertainty in their interpretation.

Any measuring equipment fulfills two tasks:

- It converts the analyte amount into an electrically measurable quantity, which is termed the signal
- It treats the signal electronically and using computing techniques.

The creation of the signal is connected with a physical, chemical, or biological interaction of the analyte within the part of the measuring instrument called the sensor, followed by conversion into a measurable electrical quantity. This section of the measuring instrument is called the transducer. The subsequent algorithmic treatment of the signal provides rough data that are further refined. The measuring procedure can be depicted as shown in **Figure 1**, from which the analyte amount/signal

conversion factor is obtained, which involves all the principal properties of the measuring system.

The analyte amount/signal conversion factor is termed the sensitivity. It follows from the scheme in **Figure 1** that the conversion factor involves many unknown parameters that are specific to the particular measuring instrument and that the sensitivity has no general significance but that it is specific for a given analytical application. The set of properties of the conversion factor is termed the characteristics of the measuring system. Two models have been formulated for determination of the measuring systems characteristics, namely, the signal model and the response model.

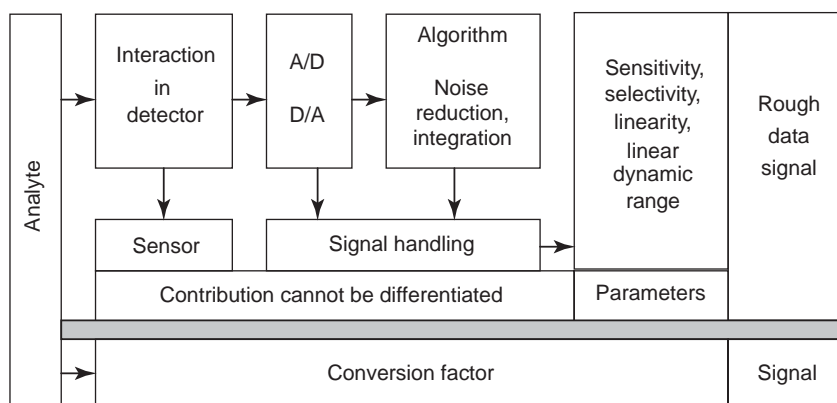

## Signal Model

The signal model expresses the relationship between the analyte signal ( $S_i$ ) and the analyte amount ( $m_i$ ). The sensitivity of the measuring instrument is expressed in terms of the product of the construction properties of the measuring instrument ( $k$ ) and a quantified physical, chemical, or biological property of the analyte ( $a_i$ ) that can be used for the measurement. It holds that

$$S_i = (k * a_i) * m_i^l \quad [1]$$

where  $l$  is the linearity coefficient.

**Figure 1** Measuring system components for an analytical method observing the traceability concept.

## Response Model

The response model, described by eqn [2], states that the real instantaneous signal of the measuring system ( $S$ ) consists of the contributions from the analyte ( $S_i$ ), from the sample matrix ( $S_{\text{matrix}}$ ), and from the instrument itself ( $S_{\text{instr}}$ ). Therefore,

$$S = S_i + S_{\text{matrix}} + S_{\text{instr}} \quad [2]$$

The analyte signal ( $S$ ) integrated from the beginning of the observation ( $t_{\text{start}}$ ) to its end ( $t_{\text{end}}$ ) is termed the response,  $R$ ,

$$R_i = \int_{t_{\text{start}}}^{t_{\text{end}}} S_i dt \quad [3]$$

Equations [1] and [2] demonstrate the variability of the measuring instruments from the point of view of the measuring principle (various physicochemical properties of analyte  $a_i$ , e.g., thermal conductivity, ionization efficiency, molar absorption coefficient) and various construction types (construction properties  $k$  and  $S_{\text{instr}}$  differ among the instrumentation manufacturers). This variability leads to differences in the measuring selectivity and linearity and to different values of the limit of detection and limit of quantitation.

## Signal Handling

The signal is the instantaneous output of the measuring instrument, usually in the form of an electrical quantity. It follows from eqn [2] that the measured signal is not a simple function of the analyte amount but that it corresponds to the sum of contributions from the analyte, the sample matrix, and the instrument itself. The contribution of the instrument,  $S_{\text{instr}}$ , is due to the construction properties

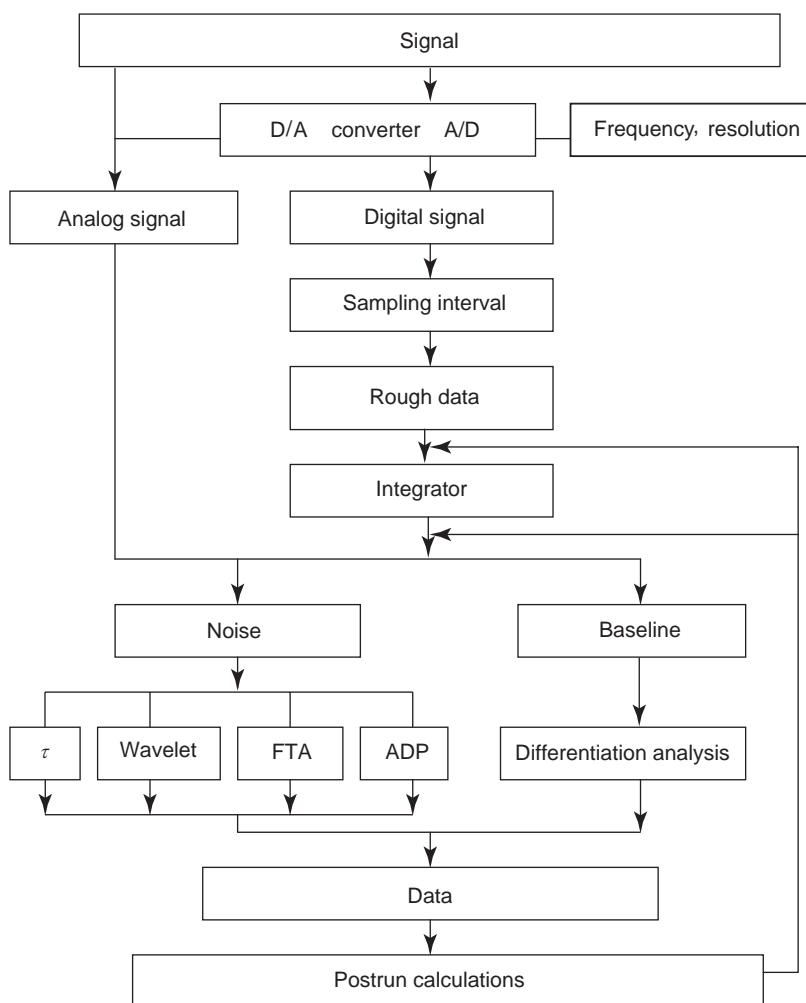

of the instrument and is called the baseline or the zero line of the system. The detection mechanism, ambient parameters, and construction materials are subject to noise, which is manifested by random increasing and decreasing of the signal. The measured signal of a detector is continuously handled and usually stored in the memory of the measuring instrument as a set of rough data that contain both the signal and the noise and the parameters of the baseline (the signal in the absence of an analyte) and are treated appropriately. A scheme of the signal treatment is shown in **Figure 2**.

The signals can be evaluated from the point of view of whether they are continuous in time or not and whether their amplitude is continuous or not. Various signal types can be distinguished (**Figure 3**), analog and digitally treated signals being most common.

The signal directly from the detector is almost always analog. It is processed in the detector, creating either an analog or digital signal that is further processed. Signals with discrete time (numerical or digital signals) are not continuous functions and are termed time series. Signals are treated in order to find their mean values, to sum or multiply them, and to reduce the noise.

The noise oscillating about the baseline is characterized by its frequency and amplitude, and as follows from statistical concepts, the sum of the positive and negative noise deviations equals zero, provided the time interval of summing is sufficiently long. A noise that has a sum of zero over the time interval of observation is called white noise. A noise that does not have a sum of zero is termed random noise. A noise that exhibits a time dependence over subsequent observation intervals is called drift (**Figure 4**). The noise is only significant within the observation interval (e.g., the elution peak width), and thus it is obvious that the significance of the various noise

**Figure 2** A scheme of treatment of the measuring instrument signal.  $\tau$  is the time constant.

	Continuous time	Discrete time
Continuous amplitude	Analog signal 	Digital signal 
Discrete amplitude	Impulse signal 	Digital signal 

**Figure 3** Classification of signals according to whether they are continuous in time and amplitude or not.

types changes with a change in the observation interval.

Various forms of the detector signal can be inter-converted by electrical components called A/D and

D/A converters (A stands for analog and D for digital) that are characterized by the conversion frequency and by the resolution format (expressed in terms of the number of bits).

**Figure 4** Noise types related to the observation interval. 1, white noise (the baseline); 2, random noise; 3, drift.

**Figure 5** Response time of a measuring instrument according to ISO 9169.

Analog signals are distorted by a number of time constants,  $\tau$ , that are proportional to the detector volume and depend on the way the signal is treated electronically. Signal distortion increases with increasing time constant and may lead to substantial suppression of the signal originally produced by rapid processes and thus to erroneous interpretation. On the other hand, analog output signals are rarely subject to white noise, and random noise is also strongly suppressed. Analog signals are visualized by recorder traces. As the time constants of recorders are rarely smaller than 0.3 s, the recorders are unsuitable for observation of processes shorter than 1 s.

In relation to the response rate of measuring instruments, the response time is defined, corresponding to the time required to attain 90% of the signal final value on a unit change in the analyte amount. The response time consists of the delay time interval

(attainment of 10% of the signal final value) and the increase or decrease interval (the dynamic behavior between 10% and 90% of the final signal). It should be emphasized that the response of nonphysical detectors (i.e., the chemical and biochemical ones) is usually nonsymmetrical, which is an important drawback of these detectors (**Figure 5**).

A digitally treated signal is produced by sampling an analog signal. The sampling consists of repetitive reading of the input (with a sampling frequency  $f$ ) over a certain time interval ( $w$ ) that is characterized by a mean value. The digital signal is not affected by the time constant and is suitable for observation of even very rapid processes because the sampling frequencies are high ( $f > 25$  kHz). However, the interval for the formation of the signal mean value is very narrow, usually  $\sim 40 \mu\text{s}$ , and thus the digital signal significantly 'copies' the noise of the analog signal.

The large number of instantaneous signal values (e.g., 25 000 values per second with a 25 kHz converter) cannot be directly used, both because the number is too large and because the values are subject to noise. Therefore, a certain time sequence of instantaneous signals is averaged over a longer time interval and the white noise is suppressed. The signal value thus obtained is characterized by an average value over a time interval that depends on the instrument construction and on the signal handling algorithm and is called a 'slice', whose values are stored in the instrument memory.

This signal handling provides rough data that represent a recording of the process observed. These rough data cannot be deconvoluted into the original signals, but their time shift compared to the original signal is negligible and does not affect the measurement result. A substantial advantage of the signal handling lies in reduction of the noise and creation of a set of data that can be evaluated repeatably.

Reduction of noise is a parallel step in the data treatment and is carried out by a number of procedures, e.g., in order of increasing sophistication,

- inclusion of the time constant ( $\tau$ );
- use of wavelets, i.e., of a digital, frequency-selective filter or band gate;
- use of Fourier transformation analysis (FTA); and
- use of adaptive digital filtering (ADF).

Appropriate software is available for all the noise reduction procedures, and the choice of approach depends on the aim of the particular analysis. The time constant approach (e.g., lengthening of the time

interval,  $t_{\text{int}}$ ) leads to suppression of all the noise types, the 'wavelet' method removes noise within a certain frequency range (digital, frequency-selective filters of the band gate (low-pass, high-pass)), FTA carries out frequency analyses over a wide range of frequencies, and ADF is a learning system capable of applying the experience obtained to new data sets.

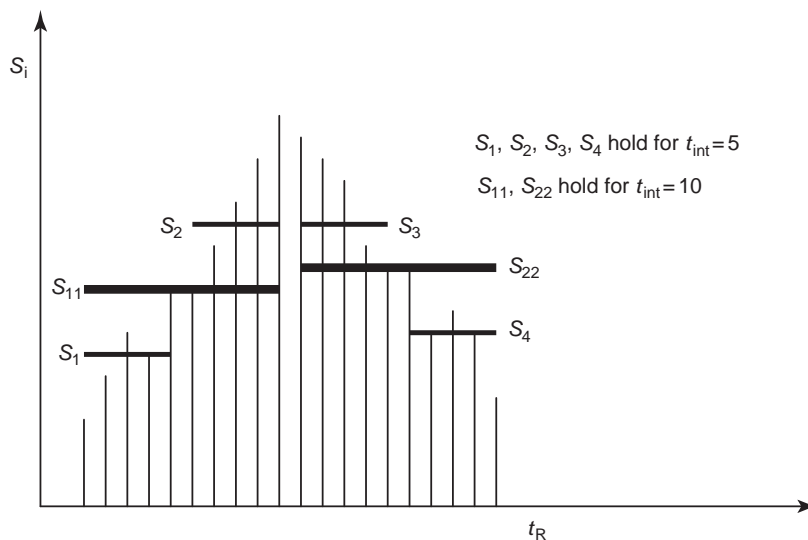

The disturbances to measurements also include sudden and intense changes in the measured signal, called spikes, originating from erroneous functioning of the measuring system. The spikes are not part of the noise because they do not exhibit a frequency structure and can only be removed during follow-up data treatment (postrun calculations). If spikes occur often, the hardware should be checked up.

The creation of a set of rough data ends the period of the 'operator passive role' in the measurement, during which the operator cannot influence the parameters of the electronic sampling, the A/D converter, the time constant of the measuring system, the slice integration interval, the parameters of the transfer of the rough data into the memory, etc.

The next phase of the signal treatment that affects the instrument calibration is an accumulation of instrument-dependent slices into an interval called a bunch, whose size is selected by the operator. During the treatment of the rough signal, all the partial signals are integrated over a certain time interval to which the mean signal value corresponds (Figure 6).

## Zero Line

In contrast to a set of rough data giving the magnitude of the overall signal, these newly created data

**Figure 6** A scheme for obtaining the mean signal value in dependence on the bunch length; this example shows the formation of four signal mean values at  $t_{\text{int}}=5$ , two values at  $t_{\text{int}}=10$ , and a single mean value at  $t_{\text{int}}=20$ .

represent signals above a predetermined zero line. The above treatment uses a suitable algorithm based on the finding that a time interval corresponding to a change in the observed process can be described by a limited number of equidistant time sections or points that are representative of the observed process. The length of the time section (bunch) depends on the character of the observed process and of the measuring method and is subject to optimization because a too-long section leads to suppression of sudden changes in the observed process, while a too-short section permits the data to be affected by noise.

If the time of the observed process changes during the measurement (e.g., the width of chromatographic peaks increases with increasing elution time), then it is necessary to maintain the number of points (bunch) describing the change constant in order to keep comparable conditions for earlier and later peaks. Under this condition, the number of rough data (slice) accumulated into a bunch increases with increasing observation time, but the observation conditions, the relative change in the signal between the bunches, the noise contribution to the signal, etc., remain independent of the observation time. The data corresponding to a bunch are characterized by the signal mean value, calculated as the mean of the slices contained in the bunch. Therefore,

$$S_{\text{bunch}} = \frac{\sum_n S_i}{n} \quad [4]$$

when the bunch length is given by

$$t_{\text{bunch}} = n * t_{\text{slice}} \quad [5]$$

where  $n$  is the number of rough data intervals and  $t_{\text{slice}}$  is the sampling interval given by the converter frequency.

This modification of the rough data suppresses random noise and permits determination of the signal zero line.

The determination of the zero signal is based on accumulation of the data into bunches, followed by differentiation analysis. It is assumed that the signal change caused by the analyte is larger than a possible random change in the zero line. It then follows from differentiation analysis of the data that the zero line corresponds to time intervals within which the first derivative of the signal lies below a certain predetermined value (the threshold value). The analytical signal is then any value whose first derivative exceeds the threshold value.

The length of  $t_{\text{bunch}}$  determines the shape of the signal zero line. If this value or the value of the signal derivative (threshold, in some data treatment software called the sensitivity) is too low, then the zero

line is subject to noise and the analyte signal can be erroneously attributed to noise. On the other hand, if the  $t_{\text{bunch}}$  or the derivative value is too large, then small changes in the analyte signal can be included erroneously in the zero signal (the baseline).

Figure 7 depicts the first derivative of a signal and demonstrates the importance of the  $t_{\text{bunch}}$  interval on the shape of the signal zero line. For a high frequency  $f_1$ , the zero line is 'not constant' because the threshold value is often exceeded; on the other hand, for a sufficiently large bunch length corresponding to  $f_3$ , the zero line is constant even at a low threshold value.

The area of an integrated signal is determined by the beginning of integration (the instant exceeding the predetermined threshold), the end of integration (the decrease in the signal first derivative below the threshold), and the zero line value between these two points. Because the analyte amount is determined from this area (sometimes from the signal height), the establishment of the zero line is decisive for the error of determination. The error increases with increasing tailing of the signal (increasing  $\tau/\sigma$  ratio) and with an increase in the ratio of the magnitudes of overlapping signals.

## Characteristics of Measuring Systems

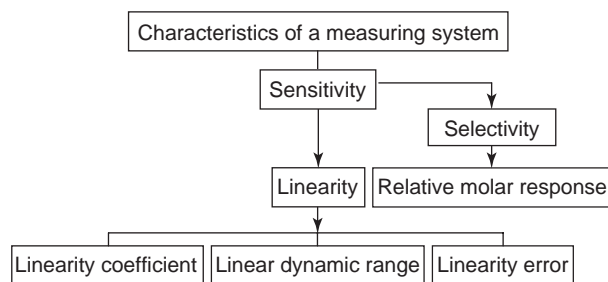

Observation in analytical chemistry is only based on interpretation of eqns [1]–[3]. It is thus understandable that evaluation of the variables in these equations has been standardized, especially in EN ISO/IEC 17025 and ISO 11843. The rules given below are in agreement with these standards and are part of the rules of good laboratory practice.

The necessity to know the properties of the conversion factor between the analyte amount and the analytical signal magnitude follows not only from the requirement of correct interpretation of the results of the measuring system but also from traceability requirements, i.e., demonstration of the chain of conversion of rough data into the analyte amount: 'traceability – property of the result of a measurement or the value of a standard whereby it can be related with a stated uncertainty, to stated references, usually national or international standards (i.e., through an unbroken chain of comparisons)' (IUPAC, 1998).

The hierarchic interconnection of the characteristics of the measuring system is shown in Figure 8 and involves the sensitivity from which the selectivity and relative molar response are derived and the linearity of the measuring system, composed of three parallel criteria, namely, the linearity coefficient, the linear dynamic range, and the linearity error.

**Figure 7** The effect of the  $t_{\text{bunch}}$  interval and of the threshold value on the determination of the signal zero value.

**Figure 8** Characteristics of a measuring system.

The sensitivity of a measuring system expresses the output/input transformation function and is the product of the construction properties ( $k$ ) and those specific to the analyte ( $a_i$ ). A rearrangement of eqn [1] leads to

$$k * a_i = \frac{S_i}{m_i^I} = \frac{1}{m_i^{(I-1)}} * \frac{S_i}{m_i} \quad [6]$$

from which it follows that the sensitivity of the measuring system will be constant and independent of the analyte amount,  $m_i$ , only when the linearity coefficient is equal to unity,  $I = 1$ . If this condition is not satisfied, then the sensitivity is a function of the analyte amount  $\frac{1}{m_i^{(I-1)}}$  and measurement over a wide analyte amount range is erroneous. Because a constant sensitivity value, independent of the analyte amount, is a prerequisite for accurate measurement, the output/input transformation function must be

linearized according to eqn [7]:

$$\sqrt[l]{k * a_i} = \frac{\sqrt[l]{S_i}}{m_i} \quad [7]$$

The dimension of the sensitivity corresponds to this definition and depends on the dimensions of the output (electrical) signal and of the input signal (analyte amount),  $\text{Vg}^{-1}$ ,  $\text{Appm}^{-1}$ ,  $\text{Hz mol}^{-1}$ ,  $\text{Vs g}^{-1}$ , etc. The dimension of the analyte amount follows from that of the sensitivity of the analytical determination.

The selectivity,  $\Gamma_i$ , expresses the ratio of the sensitivities for two analytes in a given measuring system

$$\Gamma_i = \frac{k_i}{k_{st}} * \frac{a_i}{a_{st}} \quad [8]$$

It follows from eqn [8] that the selectivity is not a general property of the measuring system and that it is always relative and dependent on the selection of the standard analyte ( $a_{st}$ ).

The ratio of the magnitudes of the analytical properties of the analyte and standard ( $a_i/a_{st}$ ) in eqn [8], e.g., the thermal conductivity or ionization potential, is called the relative molar response ( $\text{RMR}_i$ ) and is used for normalization of the response magnitudes to a unit mass amount.

The linearity of the output of a measuring system is expressed by three parameters that describe the

**Figure 9** Principal concepts of the measuring system linearity.

constant value of exponent  $l$  of the analyte amount causing signal  $S_i$  within the range of the analyte amount,  $\langle m_{i,\min}, m_{i,\max} \rangle$ , within a predetermined imprecision band (**Figure 9**). These parameters are called the linearity coefficient,  $l$ , the linear dynamic range, and the linearity error.

The linearity coefficient is defined as the slope of the  $\log(S) = -f(\log(m_i))$  dependence. It holds that

$$l = [\log S_i - \log(k * a_i)] / \log m_i \quad [9]$$

A measuring system is called linear when its linearity coefficient equals unity,  $l = 1$ . Only under this condition is the sensitivity constant and independent of the analyte amount. The linearity coefficient has the most pronounced effect on the detector signal, and it should be known for the used measuring system and the range of analyte amounts (for determination of the linearity coefficient, see below). Because the linearity coefficient is an exponential term, its effect on the signal values is large. A linearity coefficient greater than unity (e.g., with a flame-photometric detector) strongly alters the upper part of the peak and changes the value of its sharpness, whereas a linearity coefficient smaller than unity (e.g., with an electron capture detector) substantially lowers the upper part of the peak. The value of the linearity coefficient especially strongly affects large signals and thus can change the shape of an elution peak (**Figure 10**) and its characteristic quantities, e.g., efficiency, resolution, quantification. For nonunity linearity coefficients the sensitivity depends on the analyte amount (eqn [6]), and thus the determinations are subject to large errors.

**Figure 10** Distortion of the measuring system output caused by a varying linearity coefficient.

The linearity error represents a predetermined acceptable deviation from a constant sensitivity value, with a constant linearity coefficient. The linearity error is selected, and it is evident that selection of a larger error causes widening of the specified linear dynamic range but that it does not lead to improved linearization of the detector response. The linearity error should not be chosen greater than  $\pm 5\%$  to permit correct interpretation of the measured response.

**Figure 11** An example of evaluation of the measuring system parameters according to eqn [6]; the crosses denote the experimental points, the connecting line expresses the experimental changes in the calculated sensitivity.

The linear dynamic range is the range of the analyte amount within which it holds that the detector sensitivity is constant within the predetermined linearity error. Therefore, several linear dynamic ranges may exist of a measuring system, differing in the linearity coefficient. Practical measurements have a problem with distorted shapes of the response curve, as depicted in **Figure 10**. With dynamic measurements, e.g., elution profiles, the analyte passes through several linear dynamic ranges, and the detector response is a function of several linearity coefficients. Therefore, an evaluation of the instantaneous response (peak (signal) height) of the detector then leads to a more accurate representation of the function  $S = \log(m_i)$  than does an evaluation of the detector integral response.

The linear dynamic range of a measuring system can be obtained from the linearized form of the detector response, i.e., from the logarithmic form of eqn [1] (**Figure 9**) or from eqn [6], as demonstrated in **Figure 11**. The latter procedure does not permit determination of the linearity coefficient and can only indicate its deviations from unity.

Determination of the characteristics of a measuring system requires measurement of the detector response over a wide range of the analyte amount. In order to shorten the time required and to suppress errors caused by repeated analyte injection, continuous feeding of the analyte to the detector is advantageous, provided that a defined concentration profile is insured, e.g., by logarithmic dilution or through the concentration steps obtained in a step dilutor. Methods employing repeated injections of various analyte amounts are time consuming, are subject to a great dispersion, and should be used only exceptionally.

Common to all interlaboratory trials is one organization that takes responsibility for sourcing the material, sending it out

**Figure 11** An example of evaluation of the measuring system parameters according to eqn [6]; the crosses denote the experimental points, the connecting line expresses the experimental changes in the calculated sensitivity.

The linear dynamic range is the range of the analyte amount within which it holds that the detector sensitivity is constant within the predetermined linearity error. Therefore, several linear dynamic ranges may exist of a measuring system, differing in the linearity coefficient. Practical measurements have a problem with distorted shapes of the response curve, as depicted in **Figure 10**. With dynamic measurements, e.g., elution profiles, the analyte passes through several linear dynamic ranges, and the detector response is a function of several linearity coefficients. Therefore, an evaluation of the instantaneous response (peak (signal) height) of the detector then leads to a more accurate representation of the function  $S = \log(m_i)$  than does an evaluation of the detector integral response.

The linear dynamic range of a measuring system can be obtained from the linearized form of the detector response, i.e., from the logarithmic form of eqn [1] (**Figure 9**) or from eqn [6], as demonstrated in **Figure 11**. The latter procedure does not permit determination of the linearity coefficient and can only indicate its deviations from unity.

Determination of the characteristics of a measuring system requires measurement of the detector response over a wide range of the analyte amount. In order to shorten the time required and to suppress errors caused by repeated analyte injection, continuous feeding of the analyte to the detector is advantageous, provided that a defined concentration profile is insured, e.g., by logarithmic dilution or through the concentration steps obtained in a step dilutor. Methods employing repeated injections of various analyte amounts are time consuming, are subject to a great dispersion, and should be used only exceptionally.

## Introduction

One of the corner stones of quality control procedures is the analysis of test material by a number of laboratories, the so-called interlaboratory studies. The

results of the analyses allow comparisons to be made between, and information to be obtained about, the laboratories, methods, or the test materials. The laboratories may come from within an organization, or may encompass national metrology institutes across the world. The quantity value of the measurement may be known, or the object of the study may be to arrive at a consensus value. Common to all interlaboratory trials is one organization that takes responsibility for sourcing the material, sending it out

to the participating laboratories, receiving and statistically analyzing the results, and publishing a report. Exactly what is done in an interlaboratory study depends on the purpose of the study, that is what is being studied and why? In this article the different ways of setting up interlaboratory studies and the statistics used to analyze results will be described.

### Types of Interlaboratory Studies

Table 1 gives the major types of interlaboratory studies.

In each case a referee laboratory is responsible for providing the sample and organizing its distribution and the collation and analysis of the results. For the majority of studies the purpose of the study is to test the laboratory (proficiency testing), the test material (material certification), or the method (method validation study). The purpose determines some of the study parameters. For example, a method validation study requires all the laboratories to use the same method, but for other studies the method may not be prescribed. For materials certification the laboratories are chosen for their demonstrated proficiency in analysis of the material. It would not be appropriate if there was any dubiety concerning the assigned quantity value because of a suspect result.

### General Methodology

All interlaboratory studies have a common overall procedure:

1. A referee laboratory is appointed to oversee the study.

2. The participating laboratories are chosen. The criteria for choice of the number and nature of the laboratories depend on the kind of trial and will be discussed below.

3. The test material is sourced. For any interlaboratory study to be at all useful the material distributed to the laboratories must be homogeneous, i.e., each laboratory must receive a representative portion, and must be stable during transport and storage. For studies such as the Comité Consultatif de la Quantité de la Matière (CCQM) Key Comparisons in which material, often in complex matrices, is sent across the world, stability is a major concern. Homogeneity is assessed by analyzing, under repeatability conditions by a suitably precise method, at least 10 test samples. The within subsample homogeneity is established by analyzing about eight subportions of one subsample. These tests should be done for all materials that are not capable of being completely homogeneous (i.e., other than stable solutions).

4. If this is a requirement, the test material must be prepared or analyzed so that the quantity value is assigned. In interlaboratory comparisons of elements in water organized by IRMM under the International Measurement Evaluation Program (IMEP), the test materials were prepared by gravimetry or analyzed by a primary method such as isotope dilution mass spectrometry by an independent laboratory.

5. Test portions are sent to the participating laboratories with instructions and timetable for reporting measurement results.

6. On receipt of the measurement results, the organizing laboratory collates the data, and undertakes the

**Table 1** Types of interlaboratory study

<i>Name</i>	<i>Purpose</i>	<i>Comments</i>
Proficiency testing or laboratory performance study or round-robin study	To test the ability of a laboratory to obtain similar results to peer laboratories	Often employed as part of an accreditation scheme (e.g., to ISO/IEC 17025)
Cooperative trial	One-off comparison of laboratory performance	May be for contractual purposes
Material certification	To assign a consensus value to a test material	Used as part of a certification scheme, although this does not ensure traceability
Collaborative trial or method performance study or method precision study	To provide data for a validation study of a method	Determines the reproducibility precision of a method and if a CRM is used, the method or laboratory bias
Interlaboratory bias study	To determine method bias or laboratory bias of a standard method	Similar to a collaborative trial but with a specific aim
Improvement schemes	Validation of new or improved methods by comparison with fully validated method	Less costly exercise than full validation
Key comparisons	Assessment of national capability in analysis of materials	Organized by the CCQM and covers important areas related to trade, the environment and human health
IMEP		Organized by IRMM for the European Union

statistical analysis of the results. Of importance in any study is the treatment of outliers.

7. A report is distributed to the participating laboratories and may be made public as part of a process of deciding if a method is to be adopted as a standard, or if the study is a Key Comparison. Usually, the performance of individual laboratories is not disclosed by the use of codes to anonymously label the participants.

## Method Performance Study

National and international bodies that provide methods of analysis that have undergone a high level of testing and scrutiny will organize interlaboratory studies to determine the repeatability and reproducibility of a method. If the test material has a certified value then the method bias may be determined.

### Choice of Material and Laboratories

The participating laboratories should be chosen for their known ability to perform the method, or similar methods. As the method will be released for use by any competent laboratory, the choice of participants should reflect this. It may be that in a preliminary round the laboratories are sent practice samples. Indeed, a pilot trial may be done to provide an initial estimate of the precision of the method, which may give an opportunity to discontinue the study if it transpires the method does not have a minimum standard of performance. A pilot trial may also allow the method to be completely specified and any anomalies in the written procedure to be clarified before the full study.

To obtain reasonable statistics at least eight laboratories should participate in the study, although for adequate estimation of laboratory systematic errors 15 laboratories should be used.

### Measures of Precision

Repeatability precision is defined as a standard deviation of a mean result determined under conditions in which the same analyst performs a series of independent measurements of a test material with the same measurement system in a short period of time. The repeatability precision represents the smallest variability identified in an experiment.

Reproducibility precision is a standard deviation of a mean under conditions in which one or more aspects of the measurement system are changed. Interlaboratory reproducibility perforce changes the analyst, instrument, reagents, and so on. Intralaboratory reproducibility (sometimes known as intermediate

reproducibility) addresses changes within a laboratory, for example, by changing analyst, instrument, or by doing the analysis over an extended period of time.

For a method precision study, the method, of course, is fixed. The mean result  $\bar{y}$ , follows a model:

$$y_i = \bar{y} - B - \varepsilon \quad [1]$$

where  $y_i$  is the value obtained by laboratory  $i$ ,  $B$  the laboratory bias, and  $\varepsilon$  the within laboratory random error (which has an expectation of zero and standard deviation of  $s_r$ , the repeatability). Across a number of laboratories  $B$  will average to the method bias with standard deviation the between laboratory standard deviation ( $s_L$ ). Together these combine to give the reproducibility standard deviation ( $s_R$ ):

$$s_R = \sqrt{s_r^2 + s_L^2} \quad [2]$$

Thus, from the point of view of a laboratory  $B$  is a bias, while considering the interlaboratory study the  $B$ s contribute to the measurement uncertainty. This is illustrated in Figure 1.

### Method Performance Experiments

As precision is often dependent on concentration a sufficient range of samples should be chosen to obtain information across the method range. At least five (International Union of Pure and Applied Chemistry) or six (International Organization for

**Figure 1** Replicate results in a number of runs showing run bias and repeatability variance are combined to give the laboratory mean (hence laboratory bias) and intermediate reproducibility and further to the grand mean for the method (hence method bias) and reproducibility variance.

Standardization) concentration levels are recommended to be analyzed in duplicate. As the range of materials defines the limits of the study, it is up to the organizers of the study to choose an appropriate set of materials. A pharmaceutical company analyzing a product with a likely narrow range of concentration of analyte may decide to perform fewer analyses than those recommended for other materials. To avoid possible unconscious effects from a laboratory knowingly performing duplicate measurements, when results are found to have a smaller standard deviation than would have been the case in a completely blind trial, split-level experiments may be done, in which test materials having slightly different concentrations are submitted for a single analysis each.

Because the aims of method performance studies are to obtain estimates of the repeatability and reproducibility of a method, it is important that the data are shown to conform to the statistical assumptions made about them, namely that the laboratory means are distributed normally, and that there is an equality of variance among laboratories for each concentration level. A Cochran test is recommended to test the homogeneity of variances, followed by a Grubbs test for single and double outliers. Laboratory results that fail these tests should be removed from consideration as long as no more than two out of nine of the participating laboratories are so removed. If too many outliers are discovered the program is considered to be flawed and should be repeated after investigating causes of the outlying results.

If split-level samples have been sent to laboratories a Youden plot may be used to identify trends among laboratories and determine outliers. In such a plot the mean for the sample is subtracted from each result and the two results from a laboratory are plotted as a scatter plot against each other (Figure 2). Outliers are seen as isolated points away from a group, and the greater the tendency for laboratory bias, the more the points will lie in the first and third quadrants.

### Statistical Treatment of Results

If some data are missing, for example, if not all results are returned from a particular laboratory, the organizers must decide whether to include what data are reported or to exclude the laboratory altogether. Exclusion of the laboratory is generally favored unless this action would result in a lower than acceptable number of laboratories remaining for the statistical analysis.

**Figure 2** (A) Two-sample (Youden) plot of data from 10 laboratories showing a potential outlier (J) and mostly random scatter of results. (B) Two-sample (Youden) plot of data from 10 laboratories showing a potential outlier (J) and a large component of laboratory bias.

The organizing laboratory will collect the results, test for normality of variances and outliers, and then determine repeatability precision and reproducibility precision, either directly or from an analysis of variance (ANOVA) on the data. A one way ANOVA, with the laboratories being the factor studied, will give the repeatability variance as the within groups mean square, and the between groups mean square is the repeatability plus the number of replicates times the laboratory variance. For duplicate determinations these quantities may be obtained directly from the means of the two results and their differences, which will subtract out the laboratory bias.

For the  $i$ th laboratory out of  $k$  returning two measurement results,  $x_{1,i}$  and  $x_{2,i}$ , the repeatability variance is the pooled variance of  $k$  pairs of differences:

$$s_r^2 = \frac{\sum_{i=1}^{k-1} (x_{1,i} - x_{2,i})^2}{2k} = \frac{\sum_{i=1}^{k-1} d_i^2}{2k} \quad [3]$$

The sample variance, with  $k - 1$  degrees of freedom, of the means of the two measurement results ( $\bar{x}_i$ )

across the laboratories ( $s_{\bar{x}}$ ) is related to the interlaboratory variance

$$s_{\bar{x}}^2 = \frac{\sum_{i=1}^{k-1} (\bar{x}_i - \bar{\bar{x}})^2}{k-1} \quad [4]$$

where  $\bar{\bar{x}}$  is the mean of all results

$$s_L^2 = s_{\bar{x}}^2 - s_r^2/2 \quad [5]$$

from which the reproducibility variance follows from eqn [2].

The estimate of reproducibility may be compared with the expected value from the Horwitz curve. An analysis of 7500 method performance studies led to the proposal that the reproducibility expressed as a percentage of the concentration of the analyte ( $R\%$ ) was related to the concentration ( $c$ ) by

$$\log_2(R\%) = 1 - 0.5 \log_{10}(c) \quad [6]$$

where  $c$  is expressed as a fraction. For example,  $1 \mu\text{g per g} = 1 \text{ ppm} = 1:1 \times 10^{-6}$ , and hence  $R\%$  is estimated to be  $2^{1-0.5 \times (-6)} = 16\%$ . It is normally expected that a reproducibility determined in an interlaboratory study should fall within a factor of 2 of the Horwitz  $R\%$ .

Other statistical treatments that may be employed are Mandel's  $b$ - and  $k$ -statistics, box plots, and one way ANOVA when replicate data are available. When samples are analyzed at different concentrations, the relationship between precision estimates (repeatability and reproducibility) and concentration should be established.

## Reporting

Because the aim of the study is to provide information to laboratories using analytical methods, reports of method validation studies are usually made public. They comprise the specification of the analyte, a description of all materials, the number of laboratories taking part, the number of outliers, the grand mean, the assigned value (if it has been established), and the repeatability and reproducibility. The organizing panel must finally decide if the results of the study are acceptable.

## Interlaboratory Bias Study

A particular and limited form of a method performance study is one to determine the bias of a standard method, or the bias introduced by laboratories that perform the standard method. The organization of the study is much the same as for general method performance studies, but no pilot study is needed, and the number of laboratories and replicates is chosen on a statistical basis in order to

be able to determine either that the method does not have significant bias, or if the method has more than a stated *a priori* bias.

As the repeatability and reproducibility standard deviations should already be known, the values determined by the study may be tested against them by a  $\chi^2$  test. If the test reveals a significant difference, an investigation must be undertaken to decide why this is so, with possible repeats of the analyses. The method bias is calculated as the difference between the grand mean of the results of the laboratories and the assigned value of the measurand of the test material.

## Laboratory Performance (Proficiency) Tests

Proficiency tests are conducted by accrediting authorities or similar bodies as a method of comparing the performance of laboratories and maintaining their accreditation. Usually, these studies are ongoing with an appropriate frequency. Single proficiency tests, called cooperative trials, as a one-off assessment of a laboratory's ability to perform a particular test, may be undertaken among laboratories being considered for a contract for outsourced chemical analysis.

For continuing proficiency testing schemes laboratories are able to compare their measurement result (1) with their own past performance, (2) with other laboratory's present results and, if the material has an assigned value of the measurand (3) the true value.

## Organization

Unlike a collaborative trial, the organizing committee of a proficiency test must be strictly independent of the participating laboratories. As the status of the accreditation of a laboratory is often at stake the process must be scrupulously fair and must be seen to be so. In many cases the organization of a proficiency test is by a government laboratory or other statutory body. These bodies themselves can now be accredited as a statement of their competence to oversee proficiency testing schemes.

The general role of the organizer is as laid out above. It is important that all participating laboratories are aware of the rules and conditions of the test, and that they have indicated their agreement to a detailed plan. If results are to be used as part of compliance assessment to an accreditation program, then this is made clear beforehand.

## Choice of Materials, Methods, and Laboratories

The test material is chosen to be as similar to a routine sample as possible. If part of long-term trials,

the material used for each round must be different from those used in earlier rounds, and participants should be aware of this. Laboratories should not be tempted to 'second guess' the expected result from extrapolations of earlier rounds.

There is no requirement to use a particular method; only the result is of importance, but each laboratory should state the method used and the repeatability and reproducibility precision should be known. This will allow assessment of the overall performance of the laboratories against the expected precision.

Laboratories may be invited to participate as a condition of their accreditation, or through general advertisements or Internet announcements. It is recommended that all participants remain anonymous to each other and to other parties. This is not always possible or desirable. Certainly for any report of results of a round of the proficiency test the laboratories should be coded with any laboratory knowing only its own code. However, there may be some benefit from having occasional open meetings to discuss issues among laboratories. There is no requirement for any particular number of laboratories, but with fewer than five it is not possible to derive meaningful statistics. In practice, there is often a large number of laboratories (18–30 are typical) because of the economies of performing the trials. The benefit to potential customers is increased with the participation of a larger number of laboratories.

### Proficiency Test Procedures

The number of test materials will be determined by the requirements of the trial, the range of concentrations, and the matrices that must be considered. Some authorities are content with sending a single material and the harmonized protocol indicates that a maximum of six test materials should be sent out. Duplicates or split-level samples may be included, but as the laboratory must decide its own procedures these are not *a priori* necessary.

As outliers as such are laboratories that must be scrutinized and reasons for their poor performance understood, it is not good practice to remove them from consideration as happens in a method performance study. Unless there is a target mean and target measurement uncertainty (standard deviation) against which the results of all laboratories are assessed, the organizers must make a decision as to the actions to be taken with results that appear to be outlying. There are two approaches. First, outlier tests can be applied such as Cochran's test for laboratory variances (if

replicate results have been reported) or the Grubbs' test for single or two outliers of laboratory means. If one or two laboratories are rejected, the consensus mean and standard deviation of the remaining laboratories are calculated. Alternatively, a robust method is used to estimate the mean and standard deviation that can tolerate outlying results while providing useful information about the main body of laboratories.

Results are usually presented as  $z$ -scores, which are the results expressed as deviations from an accepted value (mean,  $\mu$ ) as a number of (given or target) standard deviations ( $\sigma$ ):

$$z = \frac{x_i - \mu}{\sigma} \quad [7]$$

or from sample means and standard deviations

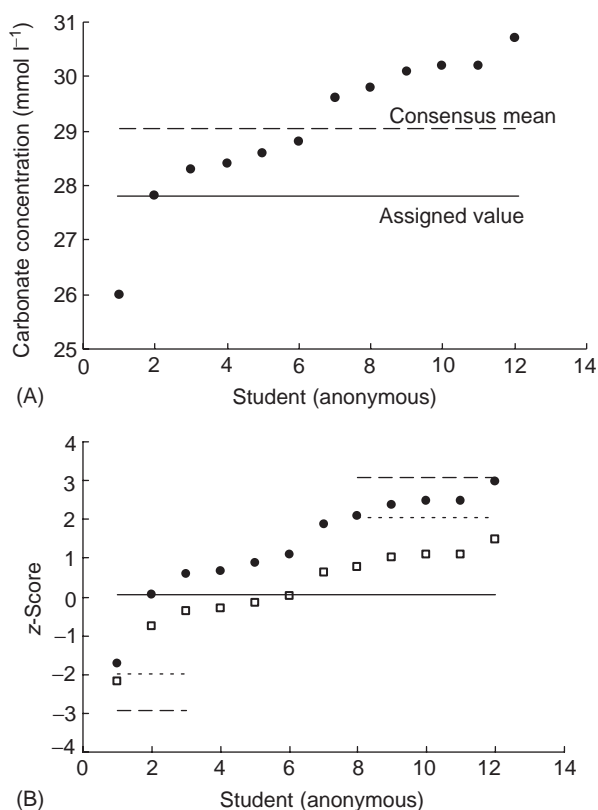

$$z = \frac{x_i - \bar{x}}{s} \quad [8]$$

Because the use of a sample mean, and particularly a sample standard deviation, relies on the assumption of normality of distribution of the data, outliers in the data must be suitably dealt with. Alternatively, robust  $z$ -scores may be calculated from the median and the normalized interquartile range (norm IQR).

$$z_{\text{robust}} = \frac{x_i - \text{median}(x)}{\text{norm IQR}} \quad [9]$$

Laboratories for which concern must be shown will be indicated as outliers or questionable results ( $2 < |z| \leq 3$ ) or extreme outliers ( $3 < |z|$ ). Where a number of samples, perhaps at different concentrations, have been analyzed a ranking method may be applied. For each sample (concentration level) the laboratories are ranked by the closeness of their results to the consensus or accepted mean, and then the ranks are summed over the samples. Laboratories with consistently bad performance will appear with the highest scores. It is also possible, but not necessarily recommended, to combine a number of  $z$ -scores from one laboratory. The sum of squared  $z$ -scores is distributed as  $\chi^2$  and as it ignores the sign of  $z$  more reflects the aim of the test, namely to highlight laboratories that have outlying results, whether too high or too low. The relative laboratory performance is the mean of the summed  $z$ -scores for a laboratory.

Figure 3 shows some data from a study conducted in the author's laboratory. Twelve students were given a test solution of a mixture of sodium carbonate and sodium bicarbonate. The results shown here are for the amount of substance concentration of carbonate. The data illustrate that

**Figure 3** (A) Ordered results from a proficiency test of 12 analysts. The amount of substance concentration of carbonate in the distributed test solution was assigned as  $27.8 \pm 0.2 \text{ mmol l}^{-1}$  with a target standard deviation for the group of  $1.0 \text{ mmol l}^{-1}$ . The consensus mean was  $28.9 \text{ mmol l}^{-1}$  with a sample standard deviation of  $1.3 \text{ mmol l}^{-1}$ . No points were outliers by a Grubbs test. (B) Data of (A) transformed to a z-score. Filled circles:  $z_i = ((x_i - \text{Assigned value}) / \text{Target standard deviation})$ , Open squares:  $z_i = ((x_i - \text{Consensus mean}) / \text{Sample standard deviation})$ . Lines are drawn at  $z = \pm 2$  and  $\pm 3$ .

significant differences in the interpretation of results can be made if the consensus mean and sample standard deviation are used to calculate z-scores. As may be seen, within the group there were no outliers, and only one student received a z-score greater than 2 ( $-2.3$ ). However, if the assigned value and a reasonable target uncertainty were applied, a number of results become suspect. Because the data contained no outliers and are symmetrically distributed about the mean, there was no great difference if the median and normalized IQR were used.

### Reporting of Proficiency Tests

The report should contain a clear statement of procedures for dealing with the data and the determination of test statistics (e.g., treatment of missing data, outliers, and method of calculation of z-scores). Usually quoted are the valid measurement results,

coded laboratory means, grand mean, and repeatability and reproducibility. Graphs of the z-scores against laboratory code, or ordered z-scores or laboratory means are often reported. Where split-level samples have been distributed, a Youden plot is usually given.

### Material Certification

Reference materials (RMs) and certified reference materials (CRMs) are used widely in quality control of analytical laboratories. Traceability of a measurement result is established through calibrators with traceable quantity values. In field laboratories making routine measurements the calibrators are usually CRMs, or working standards derived from CRMs, for which the certificate is the documentation of the traceability chain, usually to the unit in which the quantity value is expressed. At other stages in the analytical procedure RMs may be introduced to determine recovery and to establish run bias. To be a link in a traceability chain, a CRM must have its quantity value measured by comparison with a calibrator, whose value is established ultimately by the definition of the unit. A traceable quantity value is not *per se* established by the consensus of a number of laboratories, but if each of those laboratories can show they make a traceable measurement then the weight of the group of these high-level measurements is compelling evidence that the combined measurement result is as good an estimate as possible of the true value.

The organizer of an interlaboratory study to assign a quantity value to a reference material is usually a national or international certifying authority, such as the International Atomic Energy Agency (United Nations), the National Institute of Standards and Technology (USA), the Laboratory of the Government Chemist (UK), or the Community Bureau of Reference (EU).

### Choice of Materials, Methods, and Laboratories

Homogeneity and stability must be assured for the study to have any use at all. Usually, one laboratory has the responsibility for performing tests. Subsamples will be stored at different temperatures ranging from, say  $-20^\circ\text{C}$  to  $+50^\circ\text{C}$  and then analyzed once a month.

Use of a single method by a small number of laboratories runs the risk of introducing a method bias into the result. It is recommended that the laboratories are chosen for their high standard of analytical capability, and their ability to apply different methods, where this is appropriate. If necessary the laboratories will also be asked to employ different pretreatment methods. A large

number of laboratories should be chosen, with 20 in the initial phase of the certification.

### Procedure for Materials Certification

It is recommended that there be one or two rounds of preliminary tests to establish homogeneity and a likely consensus. A second round may be needed to allow understanding of any sources of inhomogeneity between laboratory results. Only those laboratories that achieve reasonable results in the initial rounds participate in the final certification round. It is important, however, to make sure that the one laboratory that does not agree with the results of the majority is not, after all, the only one with the right answer! At least eight determinations should be done in each laboratory to allow the estimation of the within laboratory repeatability. For example, four subsamples might be analyzed in duplicate. If a blank sample is also distributed, recovery experiments on the spiked blank may be performed. Samples may be distributed on different days to give information on another influence factor, time.

Normality of the distribution of results is checked by the Kolmogorov–Smirnov test and outlier tests are performed on variances and means. ANOVA is used to calculate the different contributions to the variance, between laboratory, between method, and within laboratory.

If the statistics indicate nothing untoward, the certified value is the grand mean of the results with a

95% confidence interval calculated from the standard deviation of the mean. A better estimate of the range containing the true value with 95% probability will be obtained from a full measurement uncertainty calculation, which should reflect the statistics of the trial.

### The IMEP®

In recent years, there has been an emphasis on the demonstration of national capability by the analysis of material of known composition. The IMEP® is carried out under the auspices of the European Union by the Institute for Reference Materials and Measurement (Geel, Belgium). Starting in 1989 there have been 19 rounds of IMEP®, which are detailed in Table 2.

Participating laboratories receive well-characterized samples with undisclosed values for analysis. These samples have been made, or characterized to have, certified reference values, with established traceability, and small stated measurement uncertainty. These values are established independently of any of the participating laboratories and are made known with the results of the study. This allows a direct comparison of a laboratory's result with the certified value, and so there is no requirement for statistical evaluation of means, or standard deviations that are characteristic of other studies. IMEP calls this result-oriented evaluation of measurement capacity.

**Table 2** The IMEP® rounds

<i>IMEP comparison</i>	<i>Material and matrix</i>	<i>Elements</i>	<i>Years of study</i>
19	Rice	Cu, Cd, Zn, and Pb	2002–03
17	Serum	Trace and minor constituents	2000–03
16	Wine	Pb	1999–2001
15	Water	Trace elements	2001–02
14	Sediments	Trace elements	1999–2000
13	Polyethylene	Cd, Cr, Hg, Pb, As, Cl, Br, S	1999–2000
12	Water	(Ag, B, Ba, Ca, Cd, Cu, Fe, K, Li, Mg, Mo, Ni, Pb, Rb, Sr, Tl, Zn)	2000–01
11	Car Exhaust Catalysts	Pt, Zr, Ce, Hf	1998–99
10	Polyethylene	Cd, Cr, Hg, Pb, As, Cl, Br, S	1997–98
9	Water	B, Ca, Cd, Cr, Cu, Fe, K, Li, Mg, Ni, Pb, Rb, Sr, U, Zn	1998–99
8	CO <sub>2</sub>	$n(13C)/n(12C)$ and $n(18O)/n(16O)$	1997–99
7	Human serum	Ca, Cl, Cu, Fe, K, Mg, Na, Se, Zn	1997–98
6	Water	Ag, B, Ba, Cd, Cu, Fe, Li, Mo, Ni, Pb, Rb, Sr, Tl, Zn	1994–95
5	Human serum	Fe	1991–94
4	Bovine serum	Li, Cu, Zn	1991–95
3	Water	B, Ca, Cd, Cu, Fe, K, Li, Pb, Rb, Zn	1991–93
2	Polyethylene	Cd	1990–91
1	Human serum	Li	1989

The matrices and elements that are studied target international trade, health, environmental issues, or politics that are associated with between country issues, and where possible are drawn from real-life samples. Laboratories are given the freedom to choose the method, measurands, or components that are relevant to their interests, and are encouraged to use their routine measurement methods. Usually, each laboratory is asked to report, as well as the value of the measurand, an expanded measurement uncertainty within which the value of the quantity being measured is claimed to be with a stated probability. The laboratories are also asked to indicate the method used, whether or not they consider themselves to be expert in the analysis, and to what guides or standards they may be accredited. As with any interlaboratory proficiency study full anonymity of the laboratories is guaranteed.

The results, without identifying the participating laboratories, are available on the website of IMEP<sup>®</sup> together with a breakdown by method, accreditation status, and self-certified experience. The results have been extremely illuminating, with many rounds showing little correlation between the quality of a laboratory's result and any of the collected parameters. The very first round, of lithium in serum, gave an excellent example of the problem of studies in which a consensus mean is used to compare performance. In this study, the one apparently outlying laboratory was the only one to achieve a result that was reasonable, with all other participating laboratories reporting results about twice the certified value.

## Key Comparisons of the BIPM

The Bureau International des Poids et des Mesures (BIPM) is the organization charged with overseeing the International System of Units (the SI system), and as such needs to be sure that standards maintained by nations carry the values they purport to carry. In 1999, the BIPM started the Key Comparisons program in which countries sign mutual recognition agreements (MRAs) to accept standards and if desired calibration and measurement certificates issued by other signatories' national measurement institutes (NMIs). To maintain membership of the MRA, an NMI must take part in rounds of the Key Comparisons. The Key Comparisons organized by the CCQM have consisted of a wide variety of matrices and measurands. Presently, 52 have been completed and eventually 80 are planned to cover all areas of chemical measurement. As with IMEP, the attempt is to cover all important areas that are involved in international commerce. Examples include health (cholesterol in fish), food (arsenic in fish),

environment (permanent gases in air), advanced materials (semiconductors), commodities (sulfur in fossil fuels), forensics (ethanol in air – breathalyzer), biotechnology (DNA profiling), and general analysis (pH).

Unlike the IMEP the laboratories are completely identified, as the point of the program is to demonstrate capability.

## Glossary

<b>Interquartile range (IQR)</b>	The range of values that contains the middle 50% of data
<b>Median</b>	The middle value of data arranged in order (odd number of data), or the mean of the middle two values (even number of data)
<b>Normalized interquartile range (norm IQR)</b>	norm IQR = IQR/0.735. This is an estimate of the range that encompasses 68% of the data about the median, i.e., is an estimate of the standard deviation

### Introduction

Each week, a huge number of laboratories worldwide each produce perhaps a thousand or more analytical data and report on the quality of goods, food, the quality of the environment, or on the health of patients. These results form the basis for decisions on the use of goods, or on measures to be taken for the protection of the environment or the treatment of disease. In this respect, the accuracy of analytical measurements is a prerequisite for sound decision-making. Various means to achieve accuracy are available and are applied in good laboratories in the framework of quality systems. They include the existence of a quality assurance manual, training of personnel, a good managerial structure within the laboratory, the use of validated methods, the application of statistical control principles (e.g., control charts), external quality control measures (e.g., participation in interlaboratory studies leading to confrontation with results of other laboratories), and the use of certified reference materials (CRMs). In the limited scope of this article, attention will be mainly focused on the role of reference materials (RMs) and CRMs in chemical analysis. These materials are necessary for various of the above-mentioned requirements – method validation (CRMs), internal quality control using control charts (RMs), participation in interlaboratory studies (RMs), etc. – and thus represent one of the most necessary tools for achieving good analytical quality control.

### Definitions

The following definitions of ISO (International Organization for Standardization) are relevant:

- **RM:** a material or substance, one or more properties of which are sufficiently well established to be used for the calibration of an apparatus, the assessment of the measurement method, or assigning values to materials.
- **CRM:** a reference material, one or more of whose property values are certified by a technically valid procedure, accompanied by or traceable to a certificate or other documentation that is issued by a certifying body.

CRMs respond to the definition of ‘calibrants’. However, it should be noted that ‘matrix CRMs’ are generally reserved to the validation of analytical methods and not to their calibration (with the exception of certain techniques as discussed below). Another category involves the primary reference materials (PRMs), which are certified on the basis of primary methods. According to the above definitions, four main categories of reference materials may be distinguished:

- *Pure substances or solutions* used for calibration purposes and/or the identification of substances, or aimed at testing part or the totality of an analytical procedure. They are characterized by the establishment, in mass fractions, of (i) the remaining impurities in the purified substance and/or (ii) its isotopic composition.
- *Materials with known composition* representing materials used for the calibration of certain types of instruments, e.g., certified calibrating solutions or mixtures of gases or solids prepared on a gravimetric basis.
- *Matrix RMs* representing, as much as possible, the matrix to be analyzed and being characterized or certified for given parameters (e.g., concentrations of chemical substances). They consist of samples with a natural matrix, unknown or partially known, which are primarily used for the verification of a measurement process (CRMs) and/or the evaluation of laboratory performance in the framework of interlaboratory testing schemes (RMs). These materials may be used for the calibration of certain types of measuring instruments (i.e., techniques that require calibration with a material similar to the matrix analyzed, e.g., X-ray fluorescence (XRF)).
- *Operationally defined RMs* in which the assigned or certified values are directly linked to the applied method. These materials involve parameters that are associated with a certain properties, e.g., leachable or mobilizable fractions of elements from soils and/or bioavailable fractions, or an activity (e.g., enzymatic activity). The values are defined by the applied method following a very strict analytical protocol (e.g., a standardized method).

### Role of RMs

#### Use in Interlaboratory Testing Schemes

One of the well-known uses of RMs concerns the assessment of the performance of analytical

methods or laboratories in the framework of interlaboratory studies for research (development of new methods), standardization (development of standard methods), or laboratory evaluation (proficiency testing) purposes. RMs representative of the problems to be studied are distributed to participating laboratories by a central organization. Participants are requested to perform a given number of replicate determinations of one or several specified analytes and to report their results to the organizer of the study. The results may be discussed in technical meetings, where the sources of error are identified, and may later be removed in the laboratory. By comparing different techniques with different analytical steps (e.g., different pretreatments, separation, detection, calibration modes), possible bias due to a particular technique or errors of manipulation by a laboratory may be detected. Similarly, a laboratory's performance with a given technique (e.g., a standard method) may be evaluated by comparing the results obtained by this laboratory with those of other laboratories using the same technique. It is crucial that the RMs used in such studies are homogeneous and stable.

Robust statistics are increasingly used to evaluate the performance of laboratories and/or methods in the framework of interlaboratory proficiency testing schemes. One classical approach is based on the use of  $z$  scores, calculated according to the following formula:

$$\frac{\bar{X}_{\text{measured}} - \bar{X}_{\text{ref}}}{s/\sqrt{n}}$$

where  $\bar{X}_{\text{measured}}$  is the result of the analyses of the RM(s),  $\bar{X}_{\text{ref}}$  the assigned value of the RM (or the certified value in the case of a CRM),  $s$  the standard deviation of the measurements, and  $n$  the number of replicate analyses. The  $z$  scores that are below 2 are considered to be acceptable (method/laboratory of good performance), scores between 2 and 3 correspond to critical performance (e.g., insufficient precision/quality control), and scores above 3 are not acceptable.

### Use in Quality Control Schemes

RMs may be used for the verification of the long-term reproducibility of a method by setting up control charts. A control chart is a graphical representation of how results of RM analyses vary in time; it is used to detect possible systematic fluctuations (e.g., drift) in a method. The current practice is that one RM should be analyzed with 10–20 unknown samples and the results plotted on a

**Figure 1** Example of a Shewhart control chart. The warning limit corresponds to  $\pm 2s$ , and the action line is set at  $\pm 3s$ .

graph over time. In order to detect variations that are solely due to the method, the RM used should pose the same or similar problems to the analytical chemist as the unknown samples (analytical similarity), and their composition should be homogeneous and stable in time. One commonly used chart is the Shewhart control chart (Figure 1), which fixes limits beyond which a fluctuation has a 95% or 99% probability of being of systematic origin (designated as ‘warning’ and ‘action’, respectively). The results of a method are considered to be out of control if (1) the upper or lower control limit is exceeded (‘action’), (2) the same ‘warning’ line is exceeded twice in succession, and (3) more than ten successive measurements are on the same side of the target value line (‘mean’ line representing the reference value attributed to the RM).

Other charts that are also used are the cusum (cumulative sum) charts, in which the sum of the differences between the values found experimentally and the reference value (of the RM) are plotted in time. This latter type of chart allows for a more rapid detection of drifts.

## Role of Certified RMs

### Achievement of Accuracy

When developing a new analytical method or apparatus, and after having evaluated all its critical points, the analyst has to prove the accuracy of the results obtained. Usually the results will be compared with those obtained with a classical method, which implies that the latter is fully under control in the laboratory. However, some critical factors such as the influence of laboratory contamination cannot be resolved in the laboratory itself and have to be investigated externally (through participation in interlaboratory studies; as mentioned earlier). This

allows the comparison of laboratory results with those of other, preferably outstanding, laboratories. The use of CRMs allows a similar comparison and thus represents one of the ways to assess accuracy, but whenever necessary and instantaneously. CRMs may also be used to test a standardized method when it is applied for the first time in a laboratory.

In most chemical analyses, the measurement process contains steps where the sample is physically destroyed (e.g., acid digestion, fusion, dry-ashing) or the analyte to be determined is extracted from the matrix (e.g., using organic solvents). To ensure accuracy, it is necessary to demonstrate that no losses or contamination occurs during such sample treatment. The entire analytical procedure may be verified by using a CRM with a matrix similar to the unknown sample. Disagreement between the certified value and the value determined by the laboratory indicates an error, or errors, in the analytical procedure. The user may assess his/her laboratory bias from the difference between the certified value ( $\mu$ ) and the mean value of replicate measurements ( $\bar{X}$ ):  $\bar{X} - \mu$ . The criterion for acceptance is given in ISO Guide 33 (1988) as follows:

$$-a_2 - 2\sigma_L < \bar{X} - \mu < a_1 + 2\sigma_L$$

where  $a_1$  and  $a_2$  are adjustment values chosen by the user according to economic or technical limitations or stipulations, and  $\sigma_L$  is the long-term within-laboratory standard deviation of the user's method.

The use of CRMs for validation purposes is, however, not limited to the above intralaboratory verification of trueness (checking the absence of significant systematic errors). They also enable the user to estimate the precision of a method (repeatability and reproducibility), which should actually represent one of the first steps of the method validation. In this respect, the evaluation will have to take into account specific characteristics of the CRM, in particular, possible sources of uncertainties linked to the material heterogeneity which should in principle be considered for the calculation of the uncertainty of the certified values.

RMs that are certified according to the rules laid down in ISO Guide 35 (1985) allow the user's results to be traced back to those of the international scientific community. Additionally, they enable the user to assess his/her performance at any desired moment. In this respect, examples of the use of CRMs are described in the literature and are increasingly discussed among the analytical community, which highlight the need to clarify their advantages and limitations through the production of user-friendly guidelines.

## Calibration

In most analytical procedures, calibration is carried out by means of a calibration curve using compound(s) prepared with chemicals of an appropriate purity and verified stoichiometry. Matrix effects must often be taken into account and, consequently, the calibration solutions should be matrix-matched. CRMs of pure compounds may be used for calibration. However, matrix CRMs should in principle not be used for the purpose of calibration unless no other suitable calibrants are available, with the exception of those methods (e.g., spark source mass spectrometry, wavelength-dispersive XRF, etc.) that require calibration with CRMs of a similar, fully characterized matrix (e.g., metal alloys, cements). For such methods, accuracy can only be achieved when certified RMs are used for the calibration.

## Other Uses of CRMs

CRMs can also serve the purpose of demonstrating the equivalence of methods, enabling laboratories to follow the development of new analytical instrumentation, in particular when the certification has been based on the use of different analytical techniques. The analyst may compare the performance of his/her method with those from other laboratories and/or other techniques without the need for participating in interlaboratory studies. This sort of comparison is essential when harmonization of measurements is required at an international level.

CRMs are products of very high added value. Their production and certification are very costly and, therefore, these materials should not be used for routine quality control or external quality assurance (interlaboratory studies). In order to fulfil the needs related to these uses, noncertified RMs may be prepared, linking them to one or several CRMs as a means of evaluating the accuracy of the values assigned to the so-called 'secondary' materials. This approach is straightforward in the case of calibrants (pure compounds or calibrating solutions), but is more difficult in the case of matrix CRMs owing to the likely matrix differences.

## Frequency of Use

There are no absolute rules regarding the frequency at which CRMs should be used. The verification of the accuracy of a method based on CRM analyses will actually depend on the number of analyses carried out by the laboratory, method robustness, economic considerations, legal requirements, etc. Some laboratories prefer to analyze CRMs at regular intervals (e.g., once per month) rather than performing

daily verifications through control charts, which is certainly justified for analyses that are only performed on rare occasions (involving instruments and personnel that are usually engaged in other tasks). Others base their quality control on routine measurements of (noncertified) RMs, analyzing CRMs only once a year.

CRMs should, in principle, be systematically used if important modifications are brought to a routinely applied method (e.g., instrument change, new analyst, new batch of consumables, etc.). Finally, the use of CRMs may be required by customers, e.g., when analytical data have to be used as a decision-making tool in the framework of regulations.

## Other Types of Materials

Production requirements of matrix RMs correspond to the best compromise with respect to the representativity of the materials, but they of course cannot reflect the exact reality. In some cases, however, there is a need to prepare and store samples in such a way that they closely represent specific situations. This is the case for specimen banking purposes, e.g., for environmental or medical analyses, in which samples are collected at regular intervals and stored in liquid nitrogen to ensure long-term stability. These materials are not considered as RMs *sensu stricto* but they nevertheless act as 'references' for specific programs (e.g., Environmental Specimen Banking), with the aim of following contamination trends. Their preparation follows rules similar to those used for CRMs.

## Traceability of RMs

RMs represent an important tool for demonstrating the traceability of analytical measurements to given references. One should keep in mind that the traceability of chemical analyses is often more difficult to demonstrate than for physical measurements. This is due to major differences in the measurement processes (e.g., matrix influence on chemical analyses, various analytical problems linked to the analytes and the methods used, need for sample pretreatment, etc.). Contrary to physical measurements, the calibrants and CRMs used for chemical analyses are not only used for instrument calibration but also for a variety of other purposes (e.g., method validation). In terms of traceability, the theory implies that the certified values of a substance in a CRM should be traceable to the amount of the given substance expressed according to the relevant SI unit, i.e., the mol. Since there is no 'reference mol', this traceability can be established only in relation to the mass SI unit, i.e., the kg.

The degree at which CRMs will constitute themselves a way to achieve traceability of chemical measurements will actually depend upon the quality of the link with the SI unit. In this context, the demonstration of traceability of values of matrix materials to SI is often difficult to establish owing to the variety of matrices and parameters, and of the factors that influence their analysis. Traceability in chemical analysis links may be considered as follows: SI units (kg, mol) – International calibrants (kg) – atomic masses – pure compounds – primary methods – PRMs – validated methods – matrix RMs – routine methods – (not certified) RMs. In this respect, a hierarchy of RMs could be established, following a classification established by Pan Xiu Rong in 1997. In this classification, the highest metrological quality would be achieved by PRMs developed by a national metrological laboratory (traceable to SI units and verified through international intercomparisons) and certified by a primary method, a second level would correspond to CRMs developed by either a national metrological laboratory or a specialized organization (fulfilling the conditions of ISO Guide 30) and certified using reference methods through the comparison of different methods or a combination of the two approaches, and a third level would concern working (or laboratory) reference materials developed by an accredited organization (also fulfilling the conditions of ISO Guide 30) for which reference values are established by one or more validated methods and which are accompanied by a description of the traceability and an estimate of the uncertainty. Additional details on certification are described elsewhere in this encyclopedia.

## Examples of RMs

The variety of RMs is potentially very high, considering the unlimited combination of matrix types/parameters, and the purpose of this section is not to give specific examples (which may be obtained through information sources). Let us note that 'classical' solid materials used for environmental, food, and health-related analyses (e.g., sediment, soils, molluscs, leaves, plants, vegetables, biological tissues, dairy products, etc.) are often available in the form of dried powders (either oven- or freeze-dried) stored in brown glass bottles (units containing from one to hundreds of grams). Liquid materials may involve natural waters (basically all types of waters) stored in glass ampoules, glass or polyethylene bottles, extracts (e.g., fish extracts), natural oils, biological fluids, etc. Atmospheric CRMs also exist in the form of pure gases, ashes, dusts, etc. Finally, industrial CRMs may involve alloys, glass, ceramics, paints, etc. and also pure substances used for the quality control

of comparative methods (e.g., XRF spectrometry). Assigned or certified values to the various matrices represent a huge number of parameters, e.g., inorganic substances (trace elements, nutrients, etc.), organic compounds (PAH, PCB, pesticides, dioxins, etc.), chemical forms of elements (elements in different oxidation states, organometallic compounds), extractable forms of elements (determined on the basis of operationally defined extraction procedures), etc. and also microbiological parameters (e.g., *salmonella*, *listeria*, etc.). This list is far from exhaustive, and the reader is referred to the specialized literature.

### Production and Requirements

General aspects of production and requirements are common to all types of reference materials (RMs). The main differences relate to the procedure of certification or the establishment of assigned values. In the first case (certification), the material is associated to a guarantee given by the producer regarding the certified values (homogeneity, stability, traceability, etc.), the amount produced, and the existence of an infrastructure able to ensure a proper distribution, which is not often the case for non-certified RMs generally produced at a limited scale. The production infrastructure thus depends upon the type of RM and its use. It may vary from a simple laboratory to a semi-industrial structure. The quality of the produced RMs will directly rely on the resources that are made available for their preparation (personnel, time, equipment). In this context, quality is always rewarding but it also has a cost that the producer will have to consider according to various criteria, a main one being the final use of the certified reference material (CRM). Let us recall that the general quality of an analytical work strongly depends upon the available quality control tools.

Hence, it seems obvious that the evaluation of analytical results should not only consider results obtained with CRMs but also take into consideration the way they have been prepared and used.

Driving rules for RM production are detailed in the International Standards Organization (ISO) Guide 34, which summarizes requirements regarding the production, installation, collaborators and their competence, sample handling and storage, production planning, and aspects directly related to the material preparation (including homogeneity and stability testing). One should note that the production of CRMs represents a heavy responsibility since the materials are used by the laboratories, which will check their performance on the basis of their results compared with certified values and may change their methods or way of working depending on the results obtained. This high level of responsibility goes hand-in-hand with an increasing pressure for the accreditation of certification organizations. Indeed, CRM users are increasingly demanding information on the quality of the production process. In this respect, the ISO Guide 34 gives clear instructions for the interpretation of ISO 17025 and ISO 9000 standards as regards RM production. In addition, the European Commission has issued a guide addressed to laboratories that are willing to develop RM certification projects.

of comparative methods (e.g., XRF spectrometry). Assigned or certified values to the various matrices represent a huge number of parameters, e.g., inorganic substances (trace elements, nutrients, etc.), organic compounds (PAH, PCB, pesticides, dioxins, etc.), chemical forms of elements (elements in different oxidation states, organometallic compounds), extractable forms of elements (determined on the basis of operationally defined extraction procedures), etc. and also microbiological parameters (e.g., *salmonella*, *listeria*, etc.). This list is far from exhaustive, and the reader is referred to the specialized literature.

### Production and Requirements

General aspects of production and requirements are common to all types of reference materials (RMs). The main differences relate to the procedure of certification or the establishment of assigned values. In the first case (certification), the material is associated to a guarantee given by the producer regarding the certified values (homogeneity, stability, traceability, etc.), the amount produced, and the existence of an infrastructure able to ensure a proper distribution, which is not often the case for non-certified RMs generally produced at a limited scale. The production infrastructure thus depends upon the type of RM and its use. It may vary from a simple laboratory to a semi-industrial structure. The quality of the produced RMs will directly rely on the resources that are made available for their preparation (personnel, time, equipment). In this context, quality is always rewarding but it also has a cost that the producer will have to consider according to various criteria, a main one being the final use of the certified reference material (CRM). Let us recall that the general quality of an analytical work strongly depends upon the available quality control tools.

Hence, it seems obvious that the evaluation of analytical results should not only consider results obtained with CRMs but also take into consideration the way they have been prepared and used.

Driving rules for RM production are detailed in the International Standards Organization (ISO) Guide 34, which summarizes requirements regarding the production, installation, collaborators and their competence, sample handling and storage, production planning, and aspects directly related to the material preparation (including homogeneity and stability testing). One should note that the production of CRMs represents a heavy responsibility since the materials are used by the laboratories, which will check their performance on the basis of their results compared with certified values and may change their methods or way of working depending on the results obtained. This high level of responsibility goes hand-in-hand with an increasing pressure for the accreditation of certification organizations. Indeed, CRM users are increasingly demanding information on the quality of the production process. In this respect, the ISO Guide 34 gives clear instructions for the interpretation of ISO 17025 and ISO 9000 standards as regards RM production. In addition, the European Commission has issued a guide addressed to laboratories that are willing to develop RM certification projects.

## Selection

An RM or a CRM has to fulfill a specific task and so should be selected with great care on the basis of a series of requirements. The main prerequisite is certainly that the CRM should be as representative of the real sample as possible. The most critical aspect of a method validation is indeed that the material used should be at least as difficult to analyze than samples routinely analyzed. This requirement of representativeness means, in most cases, that there should be the best possible similarity between RM and sample in:

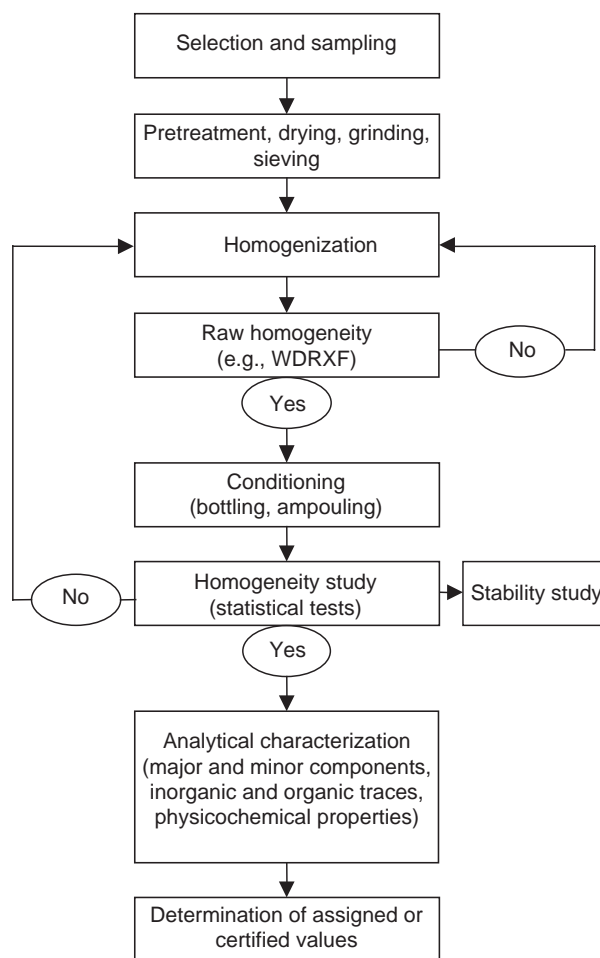

- matrix composition;
- measured substances and their level of concentrations;
- way of binding of the analytes;
- fingerprint pattern of possible interferences; and
- physical status of the material.

In selecting an RM, these factors should be carefully taken into consideration. For practical reasons, a close similarity cannot always be achieved. This actually depends on the availability of the samples and critical factors such as homogeneity and stability. For example, 'fresh' samples can hardly be stabilized and require specific treatment that will modify their physical status. Unstable chemical substances may also require specific stabilization procedures. Therefore, compromises have to be made by the producer and they have to be accepted by the user on the basis of clear justifications. In many instances, the RM preparation has to be adapted; this is discussed in the following sections.

## Preparation

An example of a planning flow chart for the preparation of an RM is shown in **Figure 1**.

The material to be used for the preparation of RMs or CRMs should be collected in a quantity sufficient to ensure an adequate and sufficiently lasting stock. The amount to be prepared depends on the analytical sample size, stability, shelf-life, and frequency of use. It may vary from 5 to 20 kg of solid material (e.g., for soils, sediments, biological tissues, etc.) or from 5 to 20 l (e.g., natural waters, calibrating solutions, etc.) for the preparation of RMs to be used in routine analysis, to up to 100 kg of solid material or several cubic meters of liquids when CRMs are to be prepared. In order to produce RMs and CRMs, laboratories need to be equipped to treat such large amounts of material without substantially changing the analytical methods. The treatment of 3–5 kg of raw material is already the limit for normal laboratory equipment and manual processing. For larger batches,

**Figure 1** Example of planning for an RM preparation. (Adapted from Muntau H (1079) *Proceedings of the First International Symposium on Production and Use of Reference Materials*, Berlin, pp. 185–218.)

and especially for larger volumes of material, it is necessary to scale up to half-industrial scale.

Typical operations required are crushing, grinding, sieving, filtering, and mixing and homogenization of the materials, which can only be performed in specialized laboratories or industries. Available tools for RM preparation are described in the literature.

## Stabilization

The usefulness of RMs and CRMs relies on the possibility offered to the laboratories to analyze them at any time, which require that their stability be guaranteed. The stabilization is, therefore, a crucial phase of the production. This required treatment should be such that it does not significantly affect the material representativeness. In this context, three types of phenomena may actually affect the

RM: physical effects, chemical reactions, and biological activity. Physical influences are generally due to effects of light or other radiations, temperature, and gravity. They can easily be avoided by adapting the storage and transport conditions. Chemical reactions may occur among substances present in the RM matrix, in particular in the case of 'fresh' materials. In the case of solid materials in a dried form, chemical reactions are either absent or are slowly processing. Storage at low temperature limits also the risk of chemical changes.

Microbial activities represent the instability factor that is the most difficult to control at the stage of RM preparation, in particular for food and environmental RMs. During treatment, it is, therefore, of paramount importance to eliminate or control the microbial activity either by killing the microorganisms or by stopping their activity for a given period. Various procedures are available to stop or limit the effects of microbial activity. RM may be heat-sterilized, which is the easiest and cheapest way, but this treatment can only be applied if the chemical substances to be analyzed/certified are not affected by very elevated temperatures (in this case, pasteurization may represent a compromise). Sterilization by gamma-irradiation is another possibility, but this process may also affect substances present in the matrix and hence the overall RM representativity. Finally, microbe destruction may be obtained by the addition of antiseptics, taking care that the added substance does not significantly affect the analytical procedure for the chemical substances to be analyzed/certified.

The stabilization of an RM has to be carefully planned, i.e., sufficiently well in advance in the overall production process to avoid further contamination or microbial growth during the subsequent steps. One should also note that the stabilization procedure may have limitations when it leads to changes that entail that the RM is no longer behaving like a 'natural' sample.

## **Treatment**

The material must be homogenized in such a way that subsamples taken in different units will be identical for the analyzed parameters (within a given confidence interval). For gases or liquids, homogenization is relatively straightforward, the only difficulty being when this operation is carried out at half-industrial scale (i.e., processing tons or cubic meters). Solid materials are more difficult to homogenize. They are generally composed of several phases, which are distributed according to various parameters such as particle size distribution and density. In principle, a narrow particle size

distribution is required to obtain similar sample intakes, which also depends on the size and density of the particles. At the planning stage of an RM preparation, it is important to define what should be the most appropriate grain sizes for a given material in order to select an adapted grinding (and if appropriate sieving) procedure. This may be particularly critical for heterogeneous materials, e.g., soils and sediments. One should also note that a very fine grinding process may lead to changes that may affect the analytical process, e.g., enhancing the extractability of some substances (because of a larger contact surface), generating static electricity for materials with very small particles (less than 1  $\mu\text{m}$ ), etc. Examples of grinding procedures and devices for RM homogenization are described in the literature.

## **Conditioning and Storage**

The vial (e.g., bottle or ampoule) in which the material will be conditioned, as well as storage conditions, should be chosen in such a way that no alteration will affect the material during and after its conditioning. The vial should be inert with respect to the RM matrix and the substances of interest so as to avoid any interactions that might generate either contamination or losses. The vial must also be such that the RM will be protected from external influences (e.g., light, temperature, humidity).

Great experience exists within RM-producing organizations, which may help in choosing the most appropriate vial and storage condition for a given matrix RM and type of substances. Optimal storage temperatures are generally determined on the basis of extensive stability experiments. As a final remark, let us note that conditioning for the transport of CRMs also has to be carefully planned in terms of both the protection of the materials and safety reasons (i.e., in the case of RM containing hazardous substances).

## **Homogeneity Study**

A subsample of an RM can be used in chemistry only once as it is generally destroyed during the analysis. Therefore, the amount of material in a bottle or ampoule should be sufficient to perform one or sometimes several determinations. The more subsamples taken, the lesser the chance that the bulk is still the same. A verification of the homogeneity must be performed to ensure that the contents within a vial and from one vial to another are the same (within- and between-vial homogeneity). The homogeneity of the material can be verified by performing, e.g., 10 replicate determinations of the element of concern within one vial (within-vial homogeneity) and by one

determination in vials set aside at regular intervals during the conditioning (2–5% of the vials can be used for this between-vial homogeneity). The coefficient of variation (CV) obtained may be compared with the CV of the final step of the method (assessed by, e.g., five replicate determinations of one digest or extract solution). Such comparison does not take into account that the extraction or digestion procedures contribute to the random uncertainty of a result; they, therefore, lead to conservative conclusions.

The minimum sample size for which the homogeneity is sufficient should be verified and provided by the producer. Below this sample size, the uncertainty caused by inhomogeneity contributes significantly to the uncertainty of the reference (or certified) values (i.e., a maximum of 30% of the total uncertainty). An additional problem is caused by segregation during transport and long-term storage, which requires that special care has to be taken for the rehomogenization of the material before taking a test portion.

## Stability Study

The material composition and the values of the RM parameters have to remain unchanged over its period of use, and this has to be demonstrated by the producer. The study of an RM's long-term stability is, of course, closely linked to the selected storage conditions. Such a study will be carried out following two basic principles: either following the possible losses of chemical substances in the sample, or detecting the apparition of known degradation products. In both cases, the verifications are based on analytical measurements, which should have a good reproducibility.

An approach to evaluate various storage conditions has been successfully used for RM certification within the last decade. It consists in studying the stability of the material stored at different temperatures (e.g., +20°C and +40°C) and to detect a possible evolution by comparing the results obtained over a given period of time (e.g., 12–24 months) with samples stored at –20°C, a temperature at which changes are assumed to be very small or negligible. The results obtained at +20°C may lead to an assessment of the sample stability at ambient laboratory temperature, whereas the results obtained at +40°C are used to assess the worst-case conditions (e.g., during transport) and allow the evaluation of the stability over longer periods of time. It is indeed assumed that a sample stable at +40°C over a period of, e.g., 1 year may be stable at +20°C for a longer period. This assumption does not hold in cases of spoilage by certain bacteria or molds having optimum temperatures for their metabolism

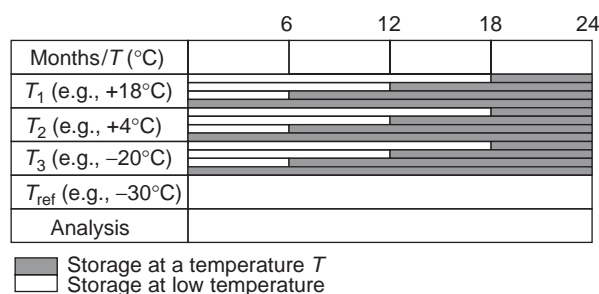

**Figure 2** Example of graph for the interpretation of results of a stability study. In this approach,  $R_T$  and  $U_T$  are the ratios (and their uncertainties) of mean results obtained at a given temperature (e.g., +20°C or +40°C) versus mean results obtained at a reference temperature (e.g., –20°C). In the ideal situation, the ratio should be 1. In practice, ratios may be comprised between  $[R_T - U_T]$  and  $[R_T + U_T]$ . In the example,  $U_T$  is equal to 0.2.

at +20–35°C, which is generally avoided thanks to a reduction of the water content of samples to less than 5% by mass and to the necessary care taken at the stabilization stage. In the framework of such experiments, results obtained at +20°C or +40°C are normalized to results obtained at –20°C, which enables to smoothen analytical variations over time. An example is shown in **Figure 2**.

The above approach is actually inspired by possible extrapolations using the Arrhenius law, which describes the activation rate in function of the temperature. Temperature is, indeed, an important factor for studying chemical reaction kinetics. The above assumption could then be backed up by such a law, e.g., materials tested at +40°C over 1 year could be assumed to be stable over 3–6 years at +20°C. In practice, however, these extrapolations are faced with difficulties linked to the complexity of RM matrices in which the kinetics of chemical reactions does not necessarily follow the Arrhenius law.

A more recent approach is based on isochronous studies in which samples are stored at different temperatures at different time intervals, performing all the analyses at the end of the study. This enables to plan the measurements well in advance and hence limits risks linked to an insufficient reproducibility of the method (which may be faced by the first approach). The drawback is that results are only available at the end of the study, which may generate a delay of the stability assessment and thus of the overall certification process. A flow chart illustrating this approach is shown in **Figure 3**.

A recent development in CRM production is the attempt to establish the maximum period over which the material may be used, which is, however, difficult to set out experimentally. Establishing such time windows is actually meant to fix the time frame

**Figure 3** Typical scheme of stability study based on isochronous measurements. (Adapted from Lamberty A, Schimmel H, and Pauwels J (1998) The study of the stability of reference materials by isochronous measurements. *Fresenius Journal of Analytical Chemistry* 360: 359–361.)

within which the producer's responsibility is legally engaged. It is not necessarily linked to the maximum period of stability of the materials.

Stability checks should be carried out at regular intervals (e.g., every 3 years) after certification, and if possible over the entire period of use of the CRM.

## Assigning or Certifying Values

Several technically valid approaches may be used to either assign reference values to or certify an RM. Table 1 describes eight modes that are followed by the National Institute of Standards and Technology (NIST), three of them leading to certified values and five used to establish 'indicative' (or assigned) values.

The certification of the purity of substances for calibration purposes represents a case apart in comparison to the approaches followed for certifying values in a matrix RM. This is usually carried out in specialized institutes (e.g., chemical companies). The basic principle is that the certified substances should be in the purest possible form, the major difficulty being that it is hardly possible to detect and quantify all potential impurities. The purity is controlled during the preparation and purification and at the end of the process. When a sufficient purity is attained, it is, therefore, possible to carry out certification analyses in order to quantify the purity and its uncertainty.

With regard to matrix RMs, the certification is less straightforward and the procedure has to follow strict rules described in the ISO Guide 35. Contrary to pure substances, matrix RMs cannot be certified on the basis of direct determinations of masses of constituents, and analytical methods have to be used that are often based on a transformation or a total destruction of the matrix. Three major approaches are described below.

**Table 1** Approaches for certifying/assigning values to a reference material

	C	A	I
1. Certification based on a primary method with confirmation by an independent method	X		
2. Certification based on two critically evaluated independent methods	X	X	
3. Certification/assignment of values based on a validated method and different methods used by external laboratories	X		
4. Assignment of values based on two or more laboratories using different methods		X	X
5. Assignment of values based on an operationally defined method		X	X
6. Assignment of values based on a single method (not responding to certification criteria)		X	X
7. Assignment of values based on external laboratories using a single method		X	X
8. Assignment of values based on data selected throughout interlaboratory studies		X	X

C means certified values, A refers to assigned values (not certified), and I corresponds to data given for information. (Adapted from Gills TE (1999) NIST standard reference materials for measurement assurance – practices, issues and perspectives. In: Fajgelj A and Parkany M (eds.) *The Use of Matrix Reference Materials in Environmental Analytical Processes*, Cambridge: The Royal Society of Chemistry, pp. 57–64.)

## Using a Primary Method in One Single Organization

The certification in this case is based on analyses carried out in one specialized laboratory, using a primary method operated by at least two independent analysts. Primary methods enable one to trace results back to SI units and hence they represent a high added value for certifying matrix RMs. In this respect, isotope dilution mass spectrometry is often used by major worldwide producers for the certification of trace elements. It should be noted that a RM certified on the basis of one single primary method may not be representative of results that will be used by routine methods. Furthermore, experience has shown that it is hardly possible to demonstrate the total absence of systematic errors for analyses carried out in a single laboratory, and producers following this approach are often checking their results through verifications with independent laboratories. It should also be noted that primary methods are not yet fully developed in analytical sectors such as the determination of trace organic or organometallic compounds, which require other approaches for assigning/certifying values (through interlaboratory studies).

### **Using Independent Reference Methods in One Single Organization**

The approach is based on the use of at least two reference methods with different chemical principles (possibly including a primary method), operated in the same laboratory by at least two independent analysts. 'Reference methods' refer to methods of which the accuracy has been demonstrated by an appropriate validation. The principle of this approach is that an agreement between two or more independent methods will limit the risk that systematic errors are left undetected. The basic question relates to the real independence of the analysts working in the same laboratory, and it is advisable to involve other laboratories, which brings us to the next case.

### **Independent Methods Applied by Several Independent Laboratories**

At least two methods (based on different chemical principles) are used by at least two independent high-quality laboratories. The most efficient approach is to develop a network of laboratories working according to clear instructions regarding certification analyses. All the methods have to be well characterized and validated. If possible, the inclusion of a primary method represents an added value with respect to the trueness of the final results. The selection of laboratories is based on their expertise in the analytical field concerned and their experience in participating in interlaboratory studies. Strict rules have to be followed for the organization of such trials, which are described in the literature. The wide variety of matrices in some fields (e.g., environmental, food analyses) generally justify such an approach, which involves several independent methods operated in expert laboratories, thus limiting the risks of systematic errors. Technical discussions among the laboratories represent an additional element that may help to improve the quality of the results. This concept relies on the assumption that there are a sufficient number of laboratories able to carry out the analytical work at a high analytical quality standard and that the differences between individual results (both within and among laboratories) are technically and statistically acceptable.

### **Voluntary Analyses through Interlaboratory Studies**

This approach corresponds to interlaboratory studies organized on a voluntary basis for specific purposes (e.g., proficiency testing). In this case, the selected laboratories and methods may be very diverse and not necessarily prepared of submitting results aimed at establishing assigned values to a RM. The

evaluation is often based on robust statistics and, while it is certainly useful for testing the performance of laboratories and/or methods, it is not recommended for the establishment of certified (or even assigned) values to a RM. The statistical evaluation of a population of results originating from various (uncontrolled) laboratories will, indeed, not replace a technical evaluation of results prior to the establishment of values to a RM. This approach is, however, followed by some organizations and has been considered in some instances as an alternative to the above described procedures.

## **Evaluation of Results**

The establishment of assigned or certified values relies on a thorough evaluation of the analytical results provided by the laboratories involved in the exercise. In this respect, one should distinguish between the technical and the statistical evaluations, which are discussed below.

### **Technical Evaluation**

The reliability of any assigned or certified values depends upon an appropriate technical evaluation, which has to be conducted prior to any statistics (which enable to study the distribution of a population of data but not to explain possible differences among them). In this respect, it is essential that the analytical method(s) used be examined in detail to verify that no systematic errors have been left undetected. In the case of certification based on an interlaboratory study, technical meetings with the participating laboratories represent a good means to scrutinize the results through discussions on the validity of the different analytical steps (e.g., extraction, separation, detection, calibration). Such technical evaluation is of particular importance for the purpose of interlaboratory-based certification, which is not solely dealing with an estimate of 'consensus values' arising from uncontrolled interlaboratory studies.

### **Statistical Evaluation**

Once a technical evaluation has been carried out, a statistical analysis is needed to confirm the absence of outlying means, examine the precision of the data, and evaluate the certified (or assigned) values and their uncertainties. A wide range of statistical tests exist in this respect; they are based on the calculation of the mean values obtained by different laboratories and/or methods and a study of their distribution, and an analysis of the variances obtained. Examples are the Dixon (Nalimov) test for the evaluation of the

distribution of means, the Cochran test to detect outlying variances, etc. As stressed above, major differences in the results should, in principle, be clarified at the stage of the technical evaluation. The basic rule is that no 'cosmetic' statistics should be used to make abstraction of data of questionable quality.

### Calculation of the Uncertainty

An important aspect of the statistical evaluation is the calculation of the uncertainty of the assigned/certified values. Recent developments through the guide for the uncertainty of measurements (GUM) are now being applied by major CRM producers to estimate the total uncertainty budget, taking account of all sources of uncertainties arising from the various production steps:

$$U_{\text{CRM}} = [u_{\text{char}}^2 + u_{\text{hom}}^2 + u_{\text{its}}^2 + u_{\text{sts}}^2]^{1/2}$$

where  $u_{\text{char}}$  is linked to the uncertainty of the material characterization (confidence interval of the certified values),  $u_{\text{hom}}$  corresponds to the variability linked to the (between-vial) homogeneity, and  $u_{\text{its}}$  and  $u_{\text{sts}}$  are related to the long-term (possible degradation during storage) and short-term (linked to possible degradation during transport) stabilities. A correct estimate of all uncertainties arising at the various production steps is not always possible, but it is recommended to examine all the sources of uncertainties, be they significant or not, to demonstrate to the users that they have been considered, whatever their order of magnitude.

The certified values will be calculated as the arithmetic means obtained by the various laboratories/methods. They will be provided with either a 95% confidence interval of the mean of laboratory means or the total uncertainty calculated according to the GUM as outlined above.

### Certificate

A certificate of analysis is mandatory for all CRMs (which is not the case for simple RMs). It contains information on the producer, a description of the material (characterization and preparation) and its use, storage recommendations, the certified values and their uncertainties, possible indicative values, identification of participating laboratories, and a legal notice with the signature of the certifying body. In some instances, a certificate may be complemented by a detailed technical report (also named certification report), which describes extensively all the production steps of the RM and provides all the individual data used for its certification along with a summary of their technical and statistical evaluations.

### Producers

The ISO Council on Reference Materials (REMCO) has identified more than 170 RM producers worldwide for the various fields of analyses. Two main bodies – the National Institute of Standards and Technology (NIST, USA) and the Institute for Reference Materials and Measurements (IRMM, European Commission, Belgium), successor of BCR (which is now a trade mark for materials produced by IRMM) – cover several fields and ensure long-term availability of the CRMs due to the large batches of materials produced. Other producers specialize in a particular field of interest, e.g., the National Research Council of Canada (NRCC, Canada), the National Institute for Environmental Studies (NIES, Japan), the IAEA Marine Environment Laboratory (Monaco), etc., specialize in marine analysis. The International Atomic Energy Agency (IAEA, Austria) mainly provides materials for nuclear measurements but also supplies RMs for non-nuclear analyses.

### Sources of Information

The REMCO publishes a directory for RMs and has gathered information on more than 1500 CRMs that were available or under preparation in 2002. In addition, the International Union of Pure and Applied Chemistry (IUPAC) issues a catalog of available CRMs. Some additional compilations of existing CRMs exist in more specialized fields, e.g., marine monitoring (publications of the National Oceanographic and Atmospheric Administration, USA).

An inventory established by the IAEA in collaboration with the UNEP program of the United Nations, and collecting information on 650 matrix RMs, may be consulted at: <http://www-naweb.iaea.org>

The major source of information on RMs, however, is the COMAR Data Bank, which is a joint enterprise between the Bundesanstalt für Materialforschung- und Prüfung (BAM, Germany), the Laboratoire National d'Essais (LNE, France), and the National Physical Laboratory (NPL, United Kingdom).

Finally, worth mentioning is the development of an 'European Virtual Institute on Reference Materials' (VI-RM), which is an initiative funded by the European Commission in which all the key players in RM production, certification, and distribution are collaborating for optimizing exchanges of knowledge and good practices.

### Introduction

It is almost a truism that the use of an analytical method implies that it will, when implemented properly, deliver a useful result. However, someone must have first described the method but is the user of the method sure that, when it was developed, enough checks were made to demonstrate its validity? This leads to a further question of what appropriate checks may be, and how the validity of the method can be demonstrated.

This article catalogs and describes the different aspects of a method that must be studied to ensure that it is, indeed, a valid method. The relationship between systematic measurements made during development and validation, the so-called development–validation cycle will be discussed. When using a previously validated method, there is still a necessity to assert that the method performs as expected in the user's laboratory. This is known as verification.

### What is Method Validation?

Definitions found in the literature emphasize different aspects of validation. For example:

- The provision of documentary evidence that a system fulfills its predefined specification...involves the evaluation of the fitness of analytical methods for their purpose.
- The process of proving that an analytical method is acceptable for its intended purpose.
- Checks...to ensure that the performance characteristics of the method are understood and

demonstrate that the method is scientifically sound under the conditions under which it is to be applied.

- Analytical measurements should be made using methods and equipment that have been tested to ensure they are fit for purpose.
- Confirmation by examination and the provision of objective evidence that the particular requirements for a specific intended use are fulfilled.

Many of these definitions use the concept of fit for purpose. The importance of this is the implication that there is no absolute worth of a method. If the results are sufficient for the requirements of the client, and the client genuinely receives useful results, the method is fit for purpose. How well a client views a method is tied to its intended use and so the process of method validation must be ultimately guided by the requirements of intended use. This appears to imply that every laboratory will need to embark on extensive experimentation with each new job. Sensibly, it is recognized that a particular method is used in a broadly similar manner across the world, and so if an international agency such as American Society for Testing and Materials or Association of Official Analytical Chemists (AOAC) takes on the job of overseeing a validation, the work of the end laboratory will be to make sure that it carries out the method in such a way as to preserve the prior validation, and documents any aspects specific to that laboratory.

The second aspect of some definitions is that validation must be seen to be done through proper documentation, objective evidence as the last definition given above (taken from International Organization for Standardization (ISO)/International Electrotechnical Commission (IEC) 17025) says. If a laboratory is seeking accreditation to ISO/IEC 17025 (general requirements for the competence of

## Method Validation

**D Brynn Hibbert**, University of New South Wales, Sydney, NSW, Australia

### Introduction

It is almost a truism that the use of an analytical method implies that it will, when implemented properly, deliver a useful result. However, someone must have first described the method but is the user of the method sure that, when it was developed, enough checks were made to demonstrate its validity? This leads to a further question of what appropriate checks may be, and how the validity of the method can be demonstrated.

This article catalogs and describes the different aspects of a method that must be studied to ensure that it is, indeed, a valid method. The relationship between systematic measurements made during development and validation, the so-called development–validation cycle will be discussed. When using a previously validated method, there is still a necessity to assert that the method performs as expected in the user's laboratory. This is known as verification.

### What is Method Validation?

Definitions found in the literature emphasize different aspects of validation. For example:

- The provision of documentary evidence that a system fulfills its predefined specification...involves the evaluation of the fitness of analytical methods for their purpose.
- The process of proving that an analytical method is acceptable for its intended purpose.
- Checks...to ensure that the performance characteristics of the method are understood and

demonstrate that the method is scientifically sound under the conditions under which it is to be applied.

- Analytical measurements should be made using methods and equipment that have been tested to ensure they are fit for purpose.
- Confirmation by examination and the provision of objective evidence that the particular requirements for a specific intended use are fulfilled.

Many of these definitions use the concept of fit for purpose. The importance of this is the implication that there is no absolute worth of a method. If the results are sufficient for the requirements of the client, and the client genuinely receives useful results, the method is fit for purpose. How well a client views a method is tied to its intended use and so the process of method validation must be ultimately guided by the requirements of intended use. This appears to imply that every laboratory will need to embark on extensive experimentation with each new job. Sensibly, it is recognized that a particular method is used in a broadly similar manner across the world, and so if an international agency such as American Society for Testing and Materials or Association of Official Analytical Chemists (AOAC) takes on the job of overseeing a validation, the work of the end laboratory will be to make sure that it carries out the method in such a way as to preserve the prior validation, and documents any aspects specific to that laboratory.

The second aspect of some definitions is that validation must be seen to be done through proper documentation, objective evidence as the last definition given above (taken from International Organization for Standardization (ISO)/International Electrotechnical Commission (IEC) 17025) says. If a laboratory is seeking accreditation to ISO/IEC 17025 (general requirements for the competence of

calibration and testing laboratories), it must use methods for which the validation can be documented for scrutiny by the assessor. In the pharmaceutical industry, the requirements of government regulators, such as the Food and Drug Administration in the USA and the Therapeutic Goods Administration in Australia, are exact and specify complete documentation of the validity of in house methods that are used in quality control of the production of drugs.

## **When Should Methods be Validated?**

The extent and timing of validation is determined by the requirements of the problem. Of course, a completely new method must be validated to show that it is indeed capable of solving the analytical problem at hand. With an established method, as improvements are made, for example, a new column in chromatography, or improved detector in spectroscopy, the method should be sufficiently revalidated to determine the performance of the novelty. A method is validated for a particular analysis, and so if the method is used for a new problem it should be revalidated. The aspects of a method that are laboratory-specific must be validated whenever changes are made, a new analyst, different instrumentation, or a move to a new laboratory. The comparison between a new method and an existing method may also be seen as validation.

The person responsible for ensuring that a method being used is appropriately valid is the analyst himself or herself. However, much of the hard work is done by international organizations who publish standard methods. These are often prescribed in legislation and it is clear that such methods have to survive the greatest scrutiny. AOAC International is a strong supporter of interlaboratory trials as the preferred way of validating methods. AOAC has introduced its Peer Verified Method Program for the validation of methods by laboratories working with only one or two others, and more recently harmonized guidelines for single laboratory method validation have been published by International Union of Pure and Applied Chemistry (IUPAC). The suite of procedures adopted by a laboratory before applying a validated method is sometimes known as verification. Many laboratories rely on published validations, but it is important that some measure of verification is done for all methods.

## **The Validation Process**

There are two levels of validating a method. First, what parameters of a method need validating must

be determined by reference to the end use, preferably in consultation with the client, or the stakeholders group. At this stage the requirements are decided. For example, a target measurement uncertainty may be specified as a particular percentage of the measurement result, or the scope of validation is set to take in changes in instrument, operator, etc.

### **Development – Validation Lifecycle**

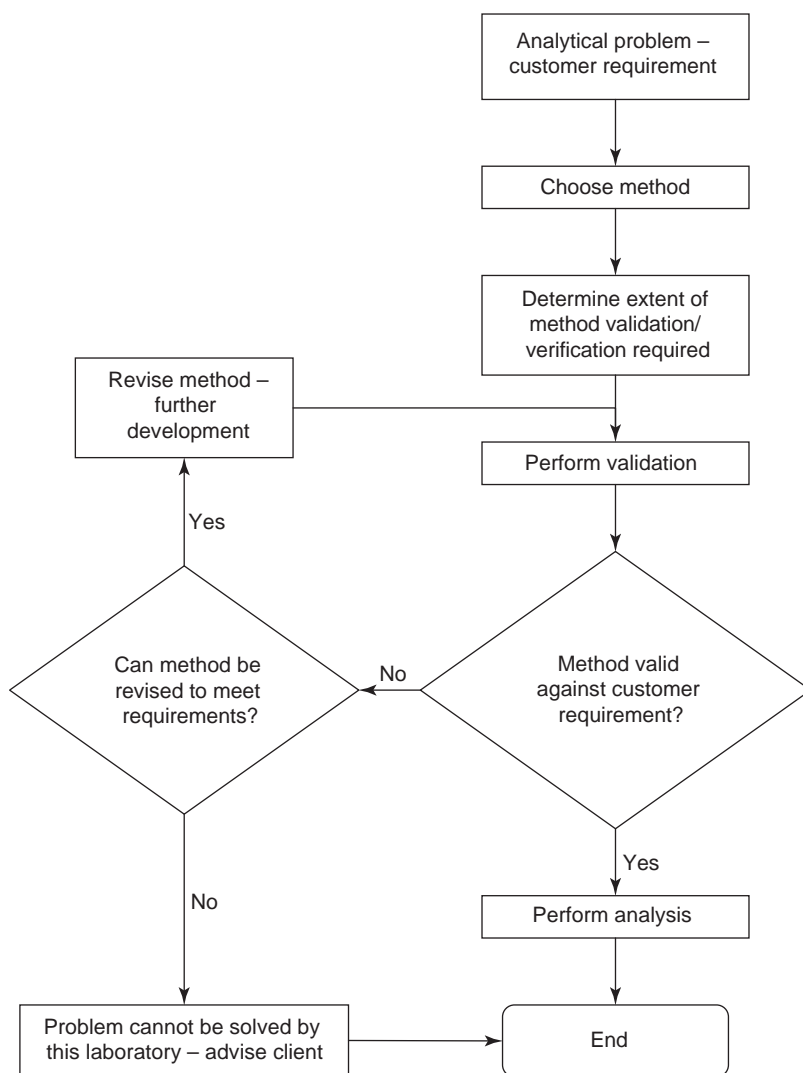

While validation is distinct from the development of method conditions it cannot be totally separated from it. Data from the development process can be used in validation studies, particularly precision data and determination of detection limits. It is unlikely that full robustness studies will have been performed during development, but if during validation it becomes evident that the method cannot meet the desired requirements then further development will be needed. Development/validation may therefore be seen as an iterated process.

The relationship between validation, development, and customer requirements is shown in **Figure 1**.

### **Validation Requirements for Different Purposes**

Methods are either valid or they are not, and it has been said that method validation is no more than the expression of the full measurement uncertainty of a method. However, historically, there are eight performance parameters that are considered to be capable of validation. These are given in **Table 1**. The hierarchy shows the order in which the validation parameters might be studied. For example, if the method does not actually analyze the required substance, then there is no point in worrying about precision or robustness.

Not all aspects of a full validation protocol are important for particular uses of some methods. For example, limits of detection or determination are not an issue for the analysis of the active in a 500 mg paracetamol tablet, but for trace impurities it is, of course, necessary to demonstrate these limits. However, in the documentation of a method validation it is useful to include each heading and at least give reasons for asserting that, as in the example above with limit of detection, one or more headings are manifestly satisfied. **Table 2** gives some examples of parameters that must be considered particularly carefully for different analytical requirements. It is stressed, however, that these are the parameters that address the particular requirements tabulated, and that other aspects might need to be validated to achieve a complete method validation.

**Figure 1** The relationship between validation, development, and customer requirements.

### Method Validation in the Pharmaceutical and Food Industries

Some highly regulated sectors, such as the pharmaceutical industry, have their own guides and regulations that must be followed. They largely concur with the more general approaches described here, but specific documents should be consulted to ensure compliance with national and international regulation. In particular, the ICH (International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use) guides cover requirements for the pharmaceutical industries in the USA, Europe, and Japan. The US has a number of regulations for the industry, published as Codes of Federal Regulations, which refer to US Pharmacopeia Compidual Methods. Use of these methods must be validated according to United States Pharmacopeial (USP) Convention

1225 – Validation of Compidual Methods. An example of regulations from other parts of the world is the Nordic Food Regulations, which govern method validation for the food industry in Scandinavia.

### Method Validation Parameters

#### Identity

It may not be trivial for an analyst to say that the method actually does measure what it purports to. When there are possibilities of speciation, or different isomers, then the analyst must be aware of the client's requirements and ensure that the method is specific for them. For example, analysis for 'total copper' is different from 'bioavailable copper', and with the latter the definition of 'bioavailable' must be carefully considered.

**Table 1** Performance parameters studied in a complete method validation

<i>Parameter</i>	<i>Description and comments</i>
Identity	
Selectivity	(Specificity). Determination of the extent of the effects of interfering substances
Limits	
of detection	Minimum result below which the presence of the analyte cannot be determined
of determination	(Quantitation). Minimum result attainable with given precision
Calibration parameters	(Linearity). Adequacy of the calibration model.
Sensitivity	Slope of a linear calibration plot. Values of coefficients of the calibration model
Trueness	(Accuracy). Demonstration of the absence of systematic error.
Recovery	The ability to determine the analyte in a given matrix
Precision	
Repeatability	Same analyst, same instrument, short time between replicates
Reproducibility	
Intralaboratory	Different analyst, instrument, longer time scale but within the laboratory
Interlaboratory	Precision between laboratories, measured in an interlaboratory study
Ruggedness	(Robustness). Ability of method to remain unaffected by small variations in method parameters Some authors make the distinction between the property robustness and a ruggedness test in which deliberate changes are made in a method in order to assess the robustness

**Table 2** Important method validation parameters for particular analytical requirements

<i>Analytical requirements</i>	<i>Important method validation parameters</i>	<i>Other validation parameters</i>
Qualitative analysis only	Selectivity, limit of detection	
Analysis of a particular form of a substance, e.g., oxidation state, isomer, conformer	Selectivity	Calibration, trueness, precision, ruggedness, (limits, recovery)
Measurement of an analyte in a matrix	Selectivity, recovery	Calibration, trueness, precision, ruggedness, (limits)
Trace analysis	Selectivity, limits of detection and determination, precision, recovery	Calibration, trueness, precision, ruggedness
Results that will be compared with those from other laboratories	Precision – interlaboratory reproducibility, trueness	Calibration, precision, ruggedness (limits, recovery)
Results that will be compared with limits or specifications	Trueness, precision, calibration parameters	Ruggedness (limits, recovery)
Method that is implemented by different analysts on different instruments	Precision – intralaboratory reproducibility, trueness, ruggedness	Calibration, precision, (limits, recovery)
Require to analyze to target measurement uncertainty	Precision	Calibration, trueness, ruggedness (limits, recovery)
A number of samples having a range of concentrations	Calibration parameters, trueness, precision	Ruggedness (limits, recovery)

A method is specific to a given analyte if it is 100% selective, i.e., there are no interferences of the analytical signal. Sometimes this may be obvious, but one of the main dangers in using a validated method for a new matrix is that novel interferences might affect the measurement result. For methods giving a signal peak, for example, gas or liquid chromatography or nuclear magnetic resonance (NMR), the peak purity must be established. This can be done in liquid chromatography by use of a multi-spectrum diode detector or by performing experiments with different columns; in mass spectrometry by increasing the mass resolution or by using a different ionization technique; and in NMR by the

use of higher field instruments or by observing different nuclei. When the likely interferences are known the response of the instrument to them can be assessed from spiking studies. Alternatively, the purity of a sample may be investigated by another more general method such as infrared spectroscopy, when the spectrum of the test sample can be compared with a library spectrum of the authentic analyte. This allows interferences that have an infrared spectrum above a certain detection limit to be deemed to be absent.

It is always better to have a method that only analyzes the desired measurand, by removing potential interfering substances in the sample preparation

or in a separation stage before detection (chromatography). If they cannot be removed, and the effect is small, then the presence of the interferent may be treated as a systematic error and either corrected for or allowed for in the measurement uncertainty. This limits the method to a particular matrix containing a particular interferent, or requires a series of experiments to quantify the effect of the interferent in all possible test samples.

Ultimately the analyst can never rule out a false positive, or the interference of some highly similar species that has not been considered. Professional judgment, the time and budget available will indicate to what extent experiments must be done to demonstrate specificity. As long as these are done and documented to the client's satisfaction, the method is considered properly validated. If a future user of the method has particular concerns about other interferences, then revalidation should be undertaken to study these substances.

## Limits

**Limit of detection** The most widely used definition of detection limit is derived from the signal of a blank plus three standard deviations of replicate blank determinations. Thus, for a linear calibration relation between concentration  $c$  and indication of the measuring system (sometimes called response)  $I$ ,

$$I = a + bc \quad [1]$$

$$c_{dl} = \frac{I_{blank} + 3s_{blank} - a}{b} \quad [2]$$

where  $s_{blank}$  is the standard deviation of 10 responses of a blank sample ( $I_{blank}$ ) performed under repeatability conditions. The use of eqn [2] presupposes that it is possible to measure a signal from a blank, or even create a sample that could be described as a blank. Not all techniques yield a sensible signal without sample, for example, ion-selective electrodes. This estimate also assumes that the blank signal is a normally distributed random variable, quite reasonable for a spectroscopic signal where the background is white noise, but not necessarily the case for all methods. Indeed, the blank signal is likely to be greatly influenced by the matrix.

If it is not possible to record a background or blank signal, the standard deviation of the blank can be estimated by the standard error of the regression of the calibration equation ( $s_{y/x}$ ) and  $I_{blank}$  by the intercept of the calibration equation ( $a$ ), when eqn [2] becomes

$$c_{dl} = \frac{3s_{y/x}}{b} \quad [3]$$

A more statistically valid approach that uses the calibration line has been recommended by IUPAC

$$c_{dl} = \frac{2t_{0.05', n-2} s_{y/x}}{b} \sqrt{\frac{1}{m} + \frac{1}{n} + \frac{\bar{c}^2}{\sum_i (c_i - \bar{c})^2}} \quad [4]$$

where  $t_{0.05', n-2}$  is the one-tailed Student- $t$  value for  $\alpha=0.05$  and  $n-2$  degrees of freedom,  $m$  is the number of replicates of the blank measurement,  $n$  the number of points in the calibration line, and  $\bar{c}$  the mean value of the calibration concentrations ( $c_i$ ). It should be noted that eqns [3] and [4] are very sensitive to the linearity of the calibration line, and may overestimate the true detection limit if  $s_{y/x}$  is large.

Whichever method is used to estimate the detection limit, it should be clearly described in the method validation.

Having estimated the minimum detectable concentration, it is always a good idea to spike a matrix with that concentration and demonstrate the instrument response to it.

**Limit of determination** There are two approaches to the limit of determination (quantitation). First, a conventional way is to define the limit in terms of the standard deviation of 10 replicates of the blank ( $s_{blank}$ ) as  $4 s_{blank}$ ,  $5 s_{blank}$ , or  $10 s_{blank}$ .

Second, a series of replicate analyses at increasing concentrations (10 at each) are performed and the standard deviation calculated at each. Usually the relative standard deviation (RSD) increases as the concentration decreases, and the limit of determination is taken as the concentration at which the RSD reaches a predetermined value.

## Calibration Equation, Range, and Analytical Sensitivity

Most modern analytical methods require calibration, because the signal that is obtained from the instrument does not give the result directly, but must be compared with a signal from one or more samples that have a known quantity value. Thus, the relationship between the measurand and the instrumental signal is established. Historically, and also for good statistical reasons, a linear calibration relation is the most common one found and desired in analytical science. In common method validation parlance, working range is defined by the maximum and minimum concentrations that the method is to be used, and linearity refers to the demonstration of a linear calibration relation across the so-called linear range. Sensitivity is the slope of the linear plot, i.e., the increase in the instrumental signal with concentration of analyte. In more general terms, with the

possibility of nonlinear calibration, and multivariate calibration, the role of method validation is to assess the adequacy of the chosen calibration model and determine the range across which it applies.

To obtain adequate statistics, the calibration range should be established by at least 10 independently prepared solutions. If a linear calibration model is assumed and the parameters of the model (slope and intercept) are determined by classical least-squares regression, the assumptions of the regression must hold. Namely:

- the model is a true description of the relationship between concentration and instrument response;
- the only errors are normally distributed in the response; and
- the errors are of constant variance across the linear range (homoscedasticity)

When constructing a linear calibration plot, we are not testing the linear relation. Hopefully this is established, for example, by Beer and Lambert in spectroscopy and Nernst in electrochemistry. It is important, however, to understand the limits of the range – the limits of detection and determination at the lower concentrations and instrumental saturation at the upper end. One procedure is to establish the lower limit as the prescribed limit of determination, then add points to the calibration until adding a further point at the high-concentration end violates some criterion. This may be when the error in the last point ( $y_n - \hat{y}_n$ ) becomes greater than an acceptable value, or when the estimation of the next point by extrapolation is not acceptable. If the measurement variance is known, the square of standard error of the regression can be compared against it by a one-sided *F*-test

$$F = \frac{\sum_{i=1}^n (y_i - \hat{y}_i)^2 / (n - 2)}{s^2} \quad [5]$$

Inspection of the calibration line itself, or using a high value of the correlation coefficient ( $r$ ) or coefficient of determination ( $r^2$ ), say better than 0.999, is not an adequate confirmation of linearity across the range, nor proof that when used to assign the concentration to a test solution it will not have unacceptable errors. A simple spreadsheet study has shown that data generated according to a nearly linear model, for example,  $y = x^{1.001}$ , and then fitted to a linear relation and used for calibration, errors of up to 70% were observed in the recovered values of  $x$ , despite  $r^2 = 0.999$ . The problem lies in the violation of the first assumption, that the data are inherently linear. Inspection of residuals is the best visual way of checking linearity. Nonlinearity,

**Figure 2** Examples of plots of residuals of calibration graphs. Top: normally distributed residuals with constant variance (homoscedastic data). Middle: data showing an increasing variance with increasing concentration (heteroscedastic data). Bottom: residual plot of a curved calibration relation.

outliers, and heteroscedacity are seen in distinctive shapes (Figure 2).

Having decided the range of the calibration, the parameters are determined from the data, making sure that at least 10 independent concentrations have been analyzed within the range. Modern spreadsheets give standard errors of the regression ( $s_{y/x}$ ) and of the slope and intercept, all of which should be quoted. The ultimate goal is to obtain the best-quality results from the calibration, and the analysis of an independent test solution, i.e., one that has not been used to construct the calibration line, is recommended. The measurement result can be compared with the assigned value, and the uncertainty calculated from

$$s_{\hat{x}_0} = \frac{s_{y/x}}{b} \sqrt{\frac{1}{m} + \frac{1}{n} + \frac{(y_0 - \bar{y})^2}{b^2 \sum_{i=1}^n (x_i - \bar{x})^2}} \quad [6]$$

where  $m$  is the number of replicates of the test solution (mean  $y_0$ ), and other terms refer to the

calibration. Equation [6] yields the 95% confidence on the estimate of  $x$  by multiplying by  $t_{0.05'', n-2}$ .

### Accuracy

Accuracy is a measure of the closeness of a result to the true value. It has two components, trueness and precision. In simple terms, lack of trueness indicates systematic error (bias in the case of instrumental results) and precision encompasses all aspects of random error.

**Trueness** Trueness is measured in terms of the systematic error (bias) in a measurement result and is the difference between a result obtained by the analyst and the true value of the measurand. For a measurement result, which is the mean of a series of analyses carried out within a single run, the bias so defined has three components, arising from the method, the laboratory, and the particular run. Assuming the method is in statistical control, the within run variation should be from a normal population with expectation zero. **Figure 3** shows these contributions to trueness. It would also be hoped that the laboratory could achieve a zero run bias. The systematic effect from the laboratory and method combined can be measured by analyzing a certified reference material (CRM) at least 10 times in several runs (assuming such material is available).

The difference between the mean result and the certified value is this bias. Collaborative trials between laboratories can establish the method bias and individual laboratory biases as shown in **Figure 3**. Collaborative trials also establish the reproducibility standard deviation.

Proficiency testing data may also be used to estimate laboratory bias.

Once bias has been estimated its magnitude is tested to decide if it is significant and must be corrected for. The bias and its uncertainty determined from the mean of repeated ( $n$ ) analyses of a CRM is

$$\delta = \bar{c} - c_{\text{CRM}} \quad [7]$$

$$u(\delta) = \sqrt{\frac{u_r^2}{n} + u^2(\text{CRM})} \quad [8]$$

where  $u_r$  is the repeatability standard deviation, and  $u(\text{CRM})$  is the uncertainty in the value of the CRM.  $\delta$  may be tested by a  $t$ -test with null hypothesis that there is no bias

$$t = \frac{|\delta|\sqrt{n}}{u(\delta)} \quad [9]$$

If the bias is deemed significant the result should be corrected. If the laboratory and method components

**Figure 3** Schematic showing the relationships among run bias, laboratory bias, and method bias. The standard deviation of the results of an interlaboratory method precision study includes the randomized components of run and laboratory bias.

are not independently known the use of the method is restricted to the laboratory in which it was validated. Bias may be a function of concentration and if this is suspected experiments should be done with a series of CRMs, to determine the proportional and fixed bias terms.

In the absence of a CRM, an uncertified reference material may be used if the analyst is satisfied that the material is well characterized enough to use for this purpose. Alternatively, a material may be analyzed by a reference method and the bias determined with respect to the reference method. Recovery studies (see below) may also give an estimate of bias.

**Precision** Precision is the closeness of agreement between results obtained under specified conditions, and is usually expressed as a standard deviation or RSD. Depending on the conditions specified, contributions may appear as bias or precision. For example, the temperature effect may be viewed as a random variable if sufficient experiments are done allowing the temperature to vary. On the other hand, if temperature is controlled and measured any difference from the target temperature can be corrected for as a bias. The measurement uncertainty is reduced, but still contains a contribution from the measurement of the effect (bias).

The repeatability is defined as the closeness of agreement between the results of successive measurements of the same measurand carried out subject to the following conditions:

- the same measurement procedure,
- the same observer,
- the same measuring instrument used under the same conditions,
- the same location, and
- repetition over a short period of time,

and the reproducibility as the closeness of agreement between the results of measurements of the same measurand, where the measurements are carried out under changed conditions such as:

- principle or method of measurement,
- observer,
- measuring instrument,
- location,
- conditions of use, and
- time.

In process control, measurements are often performed in duplicate. The difference between each measurement result may be tested against the

expected 95% probability interval of  $2 \times s_r \times \sqrt{2}$ , where  $s_r$  is the repeatability standard deviation at the specified concentration. This difference limit is known as the repeatability limit,  $r$ ,

$$r = 2 \times \sqrt{2} s_r = 2.8 s_r \quad [10]$$

When quoting reproducibility data it is important to include a statement of which aspects of the measurement system change. Standard methods that have been subjected to interlaboratory trials (interlaboratory method validation studies) quote the reproducibility as a 95% confidence interval: that is, the difference that two laboratories making measurements on portions of the same test material will exceed once in 20 times. The reproducibility precision will include the repeatability precision and components arising from the changes in the system. The relationship between this reproducibility limit,  $R$ , and the reproducibility standard deviation  $s_R$  is

$$R = 2 \times \sqrt{2} s_R = 2.8 s_R \quad [11]$$

For a laboratory performing an in-house method validation study, it is recommended that 10 test portions be analyzed at each concentration over the range of validation.

### Ruggedness (Robustness)

A method is rugged if it can remain sufficiently unaffected during normal use in which a number of changes in environmental conditions and the measurement system may occur. It is assessed by a robustness study in which deliberate changes are made and their effects determined. What is changed is chosen after consultation between analyst and client or by the professional judgment of the analyst. In the example of a robustness study of a chromatographic method parameters changed might include: column temperature, manufacturer of the column, composition of the mobile phase, and pH of the test portion. As a robustness study is a screen for unduly great changes in measurement result, it is only necessary to estimate the main (linear) effect of changing each parameter, not conduct a full determination including interaction or higher order effects. This is accomplished by a highly fractionated experimental design, such as a Plackett–Burman design in which  $(4 \times i - 1)$  parameters may be studied in  $4 \times i$  experiments ( $i = 1, 2, 3$ , etc.). Only two levels of each factor are studied, the method value and one changed by a challenging, but not ridiculous amount. A design for seven factors and eight experiments is shown in Table 3.

**Table 3** Contrast coefficients for a Plackett–Burman experimental design for seven influence factors

Experiment	Factor						
	1	2	3	4	5	6	7
1	+	+	+	–	–	+	–
2	–	+	+	+	–	–	+
3	+	–	+	+	+	–	–
4	–	+	–	+	+	+	–
5	–	–	+	–	+	+	+
6	+	–	–	+	–	+	+
7	+	+	–	–	+	–	+
8	–	–	–	–	–	–	–

The sign of the contrast coefficient indicates the level of the factor: –, normal experimental level; +, changed level.

The effect of a factor is obtained by summing each experimental response multiplied by the contrast coefficient divided by 4 (number of experiments/2).

Conventionally, the level labeled minus is the method value and the level labeled plus is the changed value. The calculation gives the average change in measurement result (which may be expressed as the change in the indication of the measuring system) when the parameter of interest changes from the method value to the changed value.

The specification of the method validation has to decide what an acceptable effect is for each factor studied.

### Recovery

Recovery is a bias usually associated with sample preparation or pretreatment. It is expressed as the measurement result as a percentage of the certified value. To obtain a proper estimate of recovery a matrix CRM should be analyzed. This value is sometimes known as the analytical yield, or apparent recovery, to distinguish it from the recovery of spiked samples described below.

If only pure analyte is available the surrogate recovery is obtained by analysis of a test material and then analyzed again after spiking with a known mass of pure analyte. The difference between the measurement results before and after spiking as a percentage

of the added material is known as the surrogate or marginal recovery. As with bias, recovery should be tested for significance and the result corrected if necessary.

## Traceability

**M Sargent**, LGC Limited, Teddington, UK

### Introduction

Traceability is one of the principal requirements for achieving comparability of measurements across

different places and different periods of time. If measurements are to be accepted everywhere, they must not only be reliable but also be made on a comparable basis to those obtained elsewhere or at other times. Hence, international quality standards such as ISO 17025 stress the need for traceability to appropriate measurement references, as well as the more familiar requirements of operating in accordance with a comprehensive quality system and using properly validated methods. Whilst it may be feasible for two results to be compared directly when necessary, a more general approach is needed to provide comparability between many results obtained at different times or places. This can be achieved by linking each measurement result to a common reference point or measurement standard. Results may then be compared through their relationship to that common reference. The concept of linking results to a stable common reference point is termed traceability.

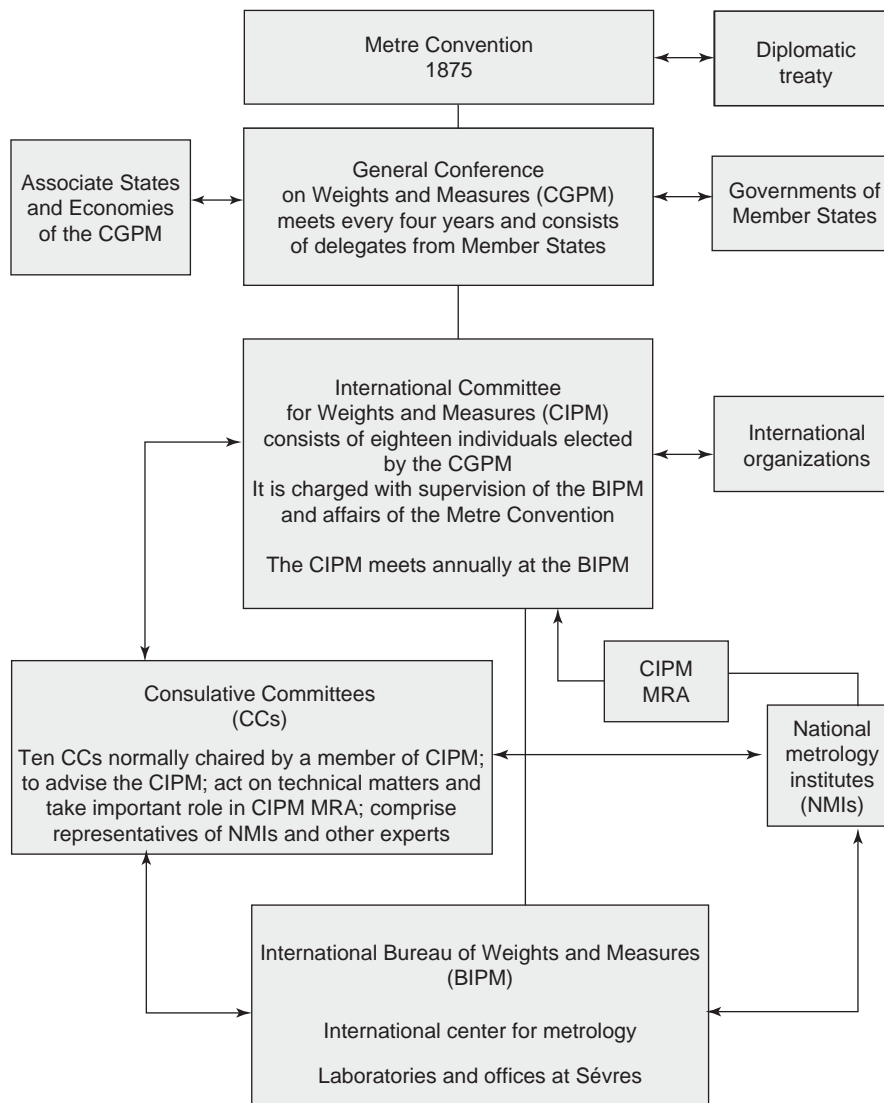

Traceability is formally defined as the property of the result of a measurement or the value of a standard whereby it can be related to stated references, usually national or international standards, through an unbroken chain of comparisons all having stated uncertainties. This definition has achieved global acceptance in the metrology community, which is responsible for physical measurements such as time, mass, or length, and metrologists have worked for well over 100 years to achieve international comparability of their measurements in this way. The outcome has been an International Measurement System that is embraced by virtually every developed country in the world. This system is described in more detail later in this article. It is timely, however, to emphasize one aspect of traceability that is often misunderstood. Traceability is not an inherent property of the internationally recognized system of measurement units (the *Système International d'Unités*, SI), such as the kilogram, meter, or mole. The concept of traceability works because a complex infrastructure has been developed within the International Measurement System to underpin the realization of these units. This infrastructure allows measurement institutes around the world to regularly intercompare their measurement standards or procedures. This provides a global basis for the reference points that these institutes use for the measurement services they provide to industry and other users. These services include traceable standards or calibration facilities that are available to end users, either directly or through secondary suppliers. The International Measurement System also provides a framework within which these institutes can

collaborate to resolve measurement differences and improve measurement techniques.

The International Measurement System underpins accurate and comparable measurements by ensuring that each measurement result for a particular parameter is traceable to a reference that is accepted throughout the world. The original point of reference for each unit was a unique artifact kept at a laboratory near Paris (see below), for example, the international standard meter or kilogram. More recently, the emphasis has been on realization of the relevant base (SI) unit as a standard of measurement, usually achieved through development of an extremely accurate measurement procedure for that parameter. In either case, the concept of traceability depends on a chain of measurements linked back to the appropriate international primary standard through a series of calibrations (i.e., comparisons between two standards in the chain). Provided that the uncertainties of the comparisons are known, a measurement result obtained through calibration against one of these standards will itself be traceable to the agreed reference.

## **Development of the International Measurement System**

The basis for international metrology was established in Paris in 1875 when a diplomatic treaty entitled the 'Convention of the Metre' was signed by representatives of 17 nations. That Convention, which was modified slightly in 1921, now has 51 Member States, including all the major industrialized countries. It remains the basis of all international agreement on units of measurement and, as mentioned above, embraces not only the traditional physical quantities but also areas such as radiation, chemistry, and biology. In order to achieve its aims, the Convention established a permanent organizational structure to enable member governments to work together on matters relating to units of measurement. The key components of this structure, which are shown in **Figure 1**, were the *Conférence Générale des Poids et Mesures* (CGPM), the *Comité International des Poids et Mesures* (CIPM), and the *Bureau International des Poids et Mesures* (BIPM). Since 1875, the need to demonstrate equivalence between national measurement standards has been met by the BIPM, which is located at Sèvres near Paris, working in collaboration with the national metrology institutes (NMIs) of the member states. The same organizations have also worked together to meet the need for measurement standards of ever increasing accuracy, range, and diversity. These

**Figure 1** The structure of the international measurement system established by the Convention of the Metre in 1875. The chart shows the key international organizations and the links between them. (Reproduced with permission from the BIPM website.)

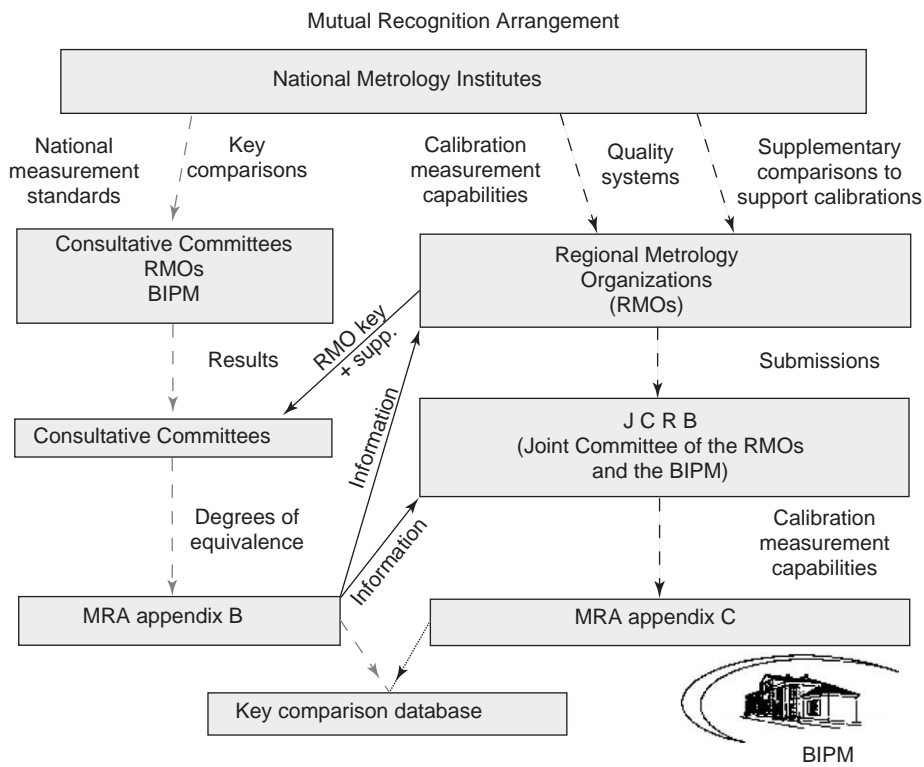

collaborative technical activities are achieved primarily through a number of Consultative Committees, each of which addresses a specific area of measurement and is normally chaired by a member of the CIPM.

A major step forward in the development of international metrology took place at a meeting held in Paris on October 14, 1999, with the establishment of a Mutual Recognition Arrangement (MRA) for national measurement standards and for calibration and measurement certificates issued by NMIs. The MRA was initially signed by the NMIs of 38 Member States and representatives of two international organizations. This Arrangement is a response to a growing need for a comprehensive scheme to give users reliable quantitative information on the

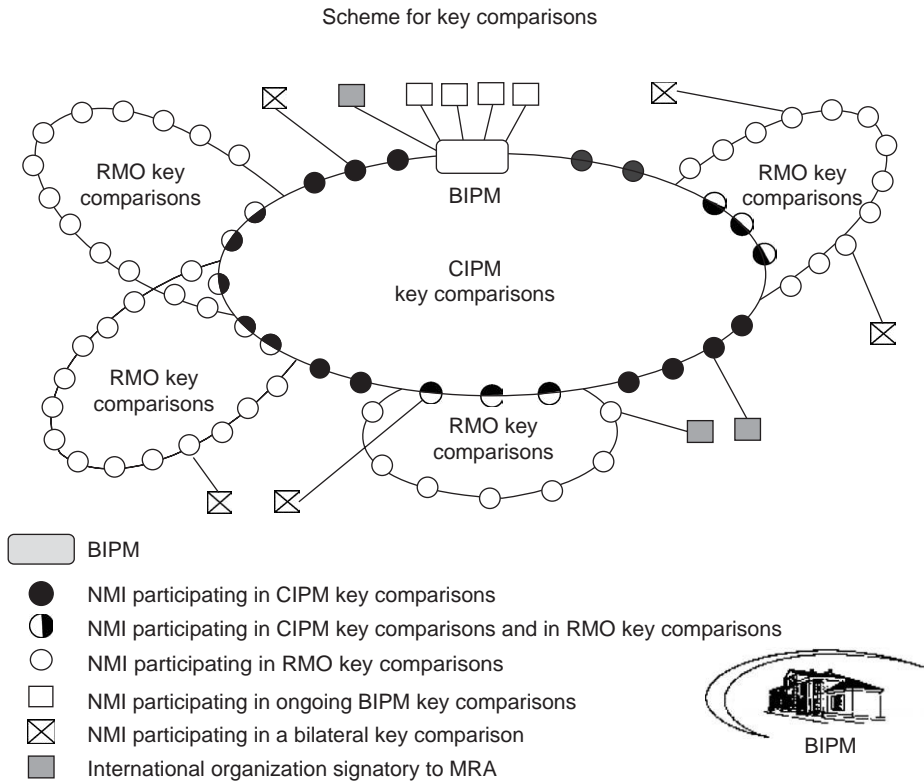

comparability of national metrology services and to provide the technical basis for wider agreements negotiated for international trade, commerce, and regulatory affairs. The organization and participation in the MRA is summarized in **Figure 2**.

A key feature of the MRA is the development of a BIPM key comparison database (KCDB), which includes the results of key and supplementary comparisons (KCs) and the calibration and measurement capabilities (CMCs) of the NMI signatories to the MRA. Key comparisons are high-level interlaboratory comparisons of the standards or measurement procedures of the participating institutes. The scheme for organizing such comparisons is shown in **Figure 3**. The comparisons are operated in the same way as proficiency testing (PT) schemes, i.e.,

**Figure 2** The organization of the BIPM Mutual Recognition Arrangement (MRA), agreed in 1999 between the directors of the national measurement institutes of 38 Member States and representatives of two international organizations. (Reproduced with permission from BIPM website.)

**Figure 3** The scheme of key comparisons established in order to support the aims of the Mutual Recognition Arrangement (MRA) and to derive the degree of equivalence between the standards or calibration services of participating national measurement institutes. (Reproduced with permission from BIPM website.)

standards or samples for intercomparison are circulated to laboratories and measured blind. Moreover, once an institute has agreed to participate in a KC it cannot withdraw its measurement results. The key comparison database is openly accessible through the BIPM website (<http://www.bipm.org>). Once agreed by the participants and approved by the relevant consultative committee, the results of each key comparison are added to the database.

The CMCs of the NMIs are also published in the key comparison database. These capabilities are submitted by each institute in accordance with the services that it offers. CMCs are subjected to two important safeguards to ensure that users of these services obtain traceable data of demonstrable equivalence with data provided by other member institutes. The safeguards are (1) the requirement that each institute should participate in relevant KCs, and demonstrate that its performance is commensurate with its claimed capabilities, and (2) a review procedure that involves experts from all MRA member institutes working at both the regional and global levels.

## The Need for Traceability in Analytical Chemistry

There are relatively few traceable chemical measurement standards in the sense used for physical measurement standards and the concept of traceable measurements is not widely understood by today's analysts. Nevertheless, the need for comparability of measurement results is just as important in analytical chemistry as in physical metrology. Classical analytical chemistry did, indeed, depend on traceable calibration of balances and volumetric glassware to achieve comparable data between laboratories. Prior to the extensive use of instrumentation, analytical laboratory procedures placed emphasis on the origin of the calibrated weights and glassware used, for example, in gravimetric or titrimetric analysis methods and the need to safeguard the integrity of these artifacts. In many analytical laboratories at that time, only a single set of balance weights was externally calibrated and traceable to a national reference; calibration of other balance weights or volumetric glassware was achieved using the set of reference weights and was an important, routine aspect of laboratory operations. In order to understand traceability in chemistry, it is important to appreciate what underlies the use of calibrated weights in this way. It will also become apparent why the concept of traceability seemed less relevant to chemistry as analytical laboratories moved away

from classical analysis and adopted instrumental techniques.

Regardless of the need for traceable calibration of balance weights and volumetric glassware, analytical chemistry is not concerned *per se* with the determination of mass and volume. Its purpose is to determine amount of substance, i.e., the amount of a specific chemical entity such as, for example, copper, potassium dichromate, or ethanol. This is reflected in the definition of the SI unit for chemistry, the mole (symbol: mol). The mole is the amount of substance of a system that contains as many elementary entities as there are atoms in 0.012 kilogram of carbon-12. When the mole is used, the elementary entities must be specified and may be atoms, molecules, ions, electrons, other particles, or specified groups of such particles. In some application areas such as, for example, the clinical sector, the mole is a widely used unit whereas in others, such as industrial or environmental analysis, it is more common to use units based on mass (e.g., milligram per kilogram) or parts per million (ppm). Nevertheless, it is important to remember that, regardless of the preferred unit, the chemist is measuring a chemical entity which must be correctly identified and for which a chemical standard is required. This is a fundamental requirement for traceability in chemistry.

In the classical analytical laboratory, it was common practice for the chemist to prepare chemical standards in-house using a knowledge of chemistry to ensure that they comprised the correct substance and were of sufficient purity for the purpose in hand. Clearly, any error in assessing the identity or purity of such a chemical standard will affect the reliability of measurements dependent on it, just as will errors in weight and volume when using an aliquot of the chemical standard to prepare a calibration solution. This situation was reflected in the growth of the chemical reagent industry, supplying initially the chemical materials and more recently certified calibration solutions. In order to ensure reliable reagents, each supplier adhered to an agreed specification, which might be its own, one agreed within an area of trade, or an international standard. These specifications were, however, largely local or sector-based; no attempt was made to adopt the concept of traceability to provide an international basis for all such materials or to implement a single, international infrastructure to underpin it.

This situation existed partly due to a widespread perception, which continues to this day, that errors in the preparation of calibration standards are not the most pressing problem facing analytical chemists. This arises because calibration using chemical standards is complicated by the dependence of the

chemical measurement process on the sample matrix. In the classical laboratory this problem was overcome by quantitative removal of the analyte from the matrix prior to measurement or by using appropriate chemistry to overcome matrix interferences. In the modern laboratory the analysis is almost invariably instrument based but the instrumental determination is often the final step of a complex analytical method involving extensive pretreatment of the sample. Hence, calibration of the instrument using a pure chemical standard, even a traceable one, is on its own insufficient to achieve reliable and comparable results.

The sample matrix problem has stimulated the development of two pragmatic solutions: matrix reference materials and interlaboratory comparisons. The matrix-matched, certified reference material (CRM) is a unique type of chemical standard commonly used to validate complete measurement methods and sometimes for instrumental calibration (e.g., in XRF). Such standards must be available for each required analyte/matrix combination. Similarly, interlaboratory comparisons are undertaken for each relevant analyte/matrix combination in order to establish comparability of data between laboratories. These comparisons range from round robin studies, which collaboratively test a new method, to formal PT schemes that assess agreement between laboratories on an ongoing basis.

CRMs and PT schemes have been used by analysts with reasonable success over many years but they both have a number of technical, practical, and economic limitations. The need for a wide variety of application-specific CRMs has led to fragmented production without any formal relationship between the certified values of CRMs produced for different applications or by different organizations. There are thousands of CRMs in use but many of those required for critical applications such as manufacturing, trade, health, or the environment are unavailable. In addition, production costs are high and it is difficult or impossible to manufacture sufficiently stable CRMs for some applications. Interlaboratory comparisons also have a number of limitations, particularly that they are time-consuming and expensive. Comparability usually extends only to the immediate participants in a single comparison because comparability between different comparisons is rarely established, even when they are coordinated by the same organization. It is impracticable to organize comparisons for every routine application or to organize a worldwide comparison involving all the laboratories requiring comparability for each measurement application.

These problems have long been recognized as a significant technical and economic limitation in

delivering sound chemical analysis data. The situation is steadily worsening with increasing demand from purchasers of data and by regulators for proven comparability of measurements. This is for several reasons. Global expansion of trade, which means more countries and more laboratories need to be brought into each interlaboratory comparison. In addition, increasing numbers of measurements are used in support of regulations, for which there is an expanding requirement for rigorously proven reliability and comparability. Finally, increasing use of subcontracted measurements, due to commercial pressures on laboratories, requires not only conformity of contractors to quality systems but also demonstration of the comparability of data from different contractors. To ensure reliable and comparable chemical measurements in the twenty-first century, it is desirable to have in place a unified international system based on the traceability of measurement results.

## **Achieving Traceability in Analytical Chemistry**

Traceable chemical measurement results require a measurement infrastructure analogous to the systems that underpin physical measurements, as described above. Chemical measurements have developed more or less on a sectorial basis and in a different culture, so that the systems developed for physical measurements cannot easily be directly applied to chemical or, indeed, biological measurements. In most countries, expertise in chemical metrology is also more widely dispersed than is the case for physical measurements, which are mainly focused on a single national measurement institute. Traceable measurements also require that the uncertainty of the entire chemical measurement procedure is fully understood. The uncertainty of the sample preparation and pretreatment is, however, largely an empirical estimate and the uncertainty associated with taking the initial sample or subsample is often overlooked. Developing reference methods that offer improved and rigorously determined levels of uncertainty for difficult sample matrices is a key factor in solving this problem.

In order to address both the technical and organizational problems, the CIPM (see **Figure 1**) decided in 1993 to establish an international, collaborative program of work in chemistry. This program is organized through the CIPM's Comité Consultatif pour la Quantité de Matière (CCQM) – the committee for metrology in chemistry. The CCQM's task is to resolve the practical difficulties of achieving comparable chemical measurements through traceability and to provide an international structure of

chemical laboratories. These laboratories are signatories to the BIPM MRA (see above) and are required to demonstrate the equivalence of their measurement data through measurement comparisons as well as implementing a quality management system for their calibration or measurement certificates. Once this has been done, claims may be submitted by each institute listing its measurement capabilities, i.e., standards or calibration services that it provides. These are vetted by peer review before inclusion in the BIPM Key Comparison Database. The CCQM has organized an ongoing series of key comparisons that reflect important applications relevant to industry, trade, health, and the environment, not just measurements on single-substance calibration standards. An example of some of the current CCQM entries in the BIPM database can be seen in Figure 4.

The results for one such Key Comparison, CCQM-K13, listed in Figure 4, are shown in Figure 5. This example illustrates a trace analysis application, the determination of lead in a sediment. The error bars

represent the expanded uncertainty reported by each participating national measurement institute. Bearing in mind that this is a difficult trace determination, these uncertainties and the degree of equivalence between the individual results (shown on the y-axis) illustrate how the participating institutes are working at the limits of current analytical methodology. This is necessary because, in order to underpin internationally traceable measurements, data from these laboratories form the ultimate reference points for calibration chains that end with routine measurements by field laboratories. Each calibration stage in such a chain introduces an increase in the uncertainty of the resulting measurement. Hence, unless the calibration chains can be kept very short, the national measurement institutes must achieve uncertainties substantially smaller than those needed by the field laboratories. As mentioned above, the BIPM Key Comparison Database provides access to the measurement capabilities of these institutes. Each such entry shows the dissemination range in terms of both the available concentration range and the

This example shows a relevant CMC for one of the institutes that participated in CCQM-K13 (illustrated in **Figure 5**). The database presently comprises several thousand CMCs, including a wide range of chemical measurements. (Reproduced with permission from BIPM website.)

corresponding range of measurement uncertainty. A typical CMC entry from one institute, for the capability tested by CCQM-K13, is shown in **Figure 6**.

## Traceability and Measurement Uncertainty

It should be clear from the above discussion that, regardless of the availability of standards, reference materials or calibration services having reference values exhibiting international traceability, the results dependent on them will not be traceable unless field laboratories are able to obtain reliable estimates of their own measurement uncertainty. This is, in fact, a requirement for accreditation to ISO 17025 but the practical difficulties of achieving it for

chemical measurements are considerable. It is well known that the uncertainties of analytical results are often large because many analytical methods require several quite complex operations (e.g., extraction, clean-up, or preconcentration) prior to the final measurement using a calibrated instrument. The uncertainty associated with these stages is frequently difficult, or sometimes impossible, to quantify and the analyst must resort to an estimate based on the available data and previous experience.

Nevertheless, it is essential that laboratories strive to achieve the best possible estimate of uncertainty at the method validation stage. A key factor in this regard is the availability of appropriate matrix reference materials. In order to achieve routine results that are both reliable and traceable, it is essential that

validation is based on materials that are both similar to the routine samples and have reference values with substantially smaller uncertainties than is required for routine data. Of equal importance is developing a base of knowledge and expertise that can help laboratories to resolve some of the problems encountered in evaluating the uncertainties of analytical results. Achieving these goals will not happen overnight but adopting the twin principles of measurement traceability and uncertainty offers analytical scientists a route map by which they may be achieved.

## Introduction

One indication of the importance of analytical chemistry is that it has been estimated that ~3% of the gross domestic product of the more advanced industrial nations is spent on analytical testing. Other indications of importance come from major areas of application of analytical science, such as: food safety, drinking water quality, animal feeds, fertilizers and pesticides; air and coastal water quality monitoring, workplace health and safety monitoring, and applications to the environment generally. Also applications in the field of health care including the quality control (QC) of pharmaceuticals, and clinical analyses for both diagnosis and to monitor the effects of

therapy; the wide area of forensic science in which analytical chemistry is a core subject; and the many and varied important industries not included in the above, in which analysis provides vital QC, and which range from the long-established, such as steel-making or dyeing, to the modern manufactures of microprocessors, optical fibers, and other advanced materials. To meet all these and many other demands, analysts produce, as a conservative estimate, over a billion items of analytical data every year in the United Kingdom alone.

It is clear from this that analytical data provide the basis for thousands of important, even critical, decisions every day of the year. Furthermore, the importance of chemical analysis is increasing as legislators, considering scientific evidence, much of which was itself derived from analytical chemistry, continue to frame regulatory requirements, which can be enforced only by the endeavors of skilled analysts.

With matters of public health and safety, the reliability of manufactured products, the protection of the environment, and even the freedom of individuals depending on their results, analysts ought not to be surprised that those who pay for, use, or are affected by their data seek reassurance that the data are both reliable and fit for their intended purposes.

Analytical chemists recognize their responsibilities for the data they report and by their training and experience come to recognize many of the likeliest sources of significant errors in their methods. However, the point must be made that as analytical equipment becomes more automatic, instrumental, and computerized, the analyst must increasingly rely on indirect evidence that his analyses are proceeding as planned. Similarly, when quantities of sample and analyte are too small to be visible, the analyst has to depend on instrumental settings and readouts as being reliable indicators of experimental conditions. These difficulties have arisen during the same period that universities and training colleges have been obliged to provide an ever-broader range of practical experience at some sacrifice to the depth of understanding, whilst the problems that analysts are called upon to tackle have become increasingly complex.

The traditional approaches to assure the quality of analytical data involved careful standardization of reagents, accurate measurements of volumes, working to standard methods, replications of analyses, 'blind' analyses, and the use of reference materials. Other methods included participation in cooperative or 'round robin' analysis schemes with laboratories doing similar work, the witnessing of analysis, and verification and even certification of analysis by an independent laboratory. All these approaches are still in use along with other variants of QC, but it is now widely recognized that QC alone does not provide a high level of confidence without incurring very large costs, and that another rational approach is to ensure that all analytical and supporting staff are fully trained in and follow written instructions, and maintain appropriate records, of all the stages in the analytical process from the arrival of the sample in the laboratory to the reporting of the findings to the customer. A complete set of written procedures, training, practical activities, and records are known as the 'quality system'. Quality systems have been published as standards for companies, such as the widely known BS EN ISO 9000: 2000 series and Good Manufacturing Practice (GMP). Quality standards for laboratories include BS EN ISO 17025: 2000, 'General requirements for the competence of testing and calibration laboratories'; Good Laboratory Practice (GLP), which applies to laboratories involved in any testing of materials for toxicological

purposes; and Clinical Pathology Accreditation, specifically for the accreditation of pathology laboratories. The ISO 17025 standard is the most widely applied and is the main focus of this article.

One other development in support of analytical data quality must be mentioned, namely the use of 'round robin' analysis, which has developed into a number of laboratory performance assessment programs, and also known as proficiency-testing schemes. A proficiency-testing scheme does not eliminate the need for a quality system. In fact, the scheme can at best provide only a 'snapshot' of how a laboratory was performing on particular analyses on one occasion. Moreover, such schemes still exist only for a fairly limited range of sample and analyte combinations.

## **Analytical Quality Assurance**

The control and assurance of the quality of analytical data are important features of laboratory management. Since the great majority of analytical laboratories exist to provide services to customers in the same or other organizations, the appropriate definitions of quality are 'meeting customer requirements' and 'being fit for the intended purpose'. These do not wholly describe the situation of the analyst. Thus, it cannot be assumed that all customers really want unbiased analytical results when biased data might provide commercial advantage. Many analytical laboratories, especially those providing contract services to a wide range of industries, are not always told by their customers what their requirements are, and they might not know themselves. The best that the analyst can do in such situations is to exercise professional judgment based on experience and whatever knowledge they have of the industry concerned.

The term 'quality control' is used differently around the world. In the Far East, particularly Japan, it refers to what the Western industrial nations call quality assurance (QA), which is discussed shortly. QC in the West refers to the process of monitoring the product to establish whether or not it conforms to specified requirements, for example to demonstrate that a manufactured batch of a chemical used as a pharmaceutical raw material meets all the requirements of the specification published in the British Pharmacopoeia. In fact, this is not true QC, other than to prevent the release and use of substandard product. It only assesses quality, after the process is complete, and this is both costly and of limited operational use. In the analytical laboratory, QC refers to the analyses conducted along with a batch of samples, the results of which are used to judge whether the analyses were made correctly. For this

purpose, the QC sample may be made using previously or independently analyzed samples, reference substances, spiked samples, proficiency-testing samples, or simply replicates used to estimate precision. The criticism made above is valid; the QC results give data after the event. Moreover, unless the QC samples are 'blind' and introduced randomly, the information yielded by them could be biased.

The approach of QA is not, as sometimes stated, to replace QC, and neither is it an alternative name for QC, although some confusion exists about this. QA seeks to implement a system (the quality system) for managing all the operations and other features of a process that are known to influence quality, and QC forms part of that system. In the laboratory, this means not only the analytical methodology but all the other inputs, from the original customer instruction to sample storage and handling, the equipment and reagents used, and any calibrations made on them, all documentation, the environment in which the work was performed, the training and experience of the analyst, and finally, because the product is data, reporting the analyst's findings to the client in the most appropriate form.

Most laboratories have, in practice, developed their own approaches to handling these aspects of QA, but often they are not complete for various reasons. One purpose of the several standards mentioned in the section 'Introduction' is to provide complete systems. These and other successful private, official, and industry-based standards for analytical QA systems address a number of common features including:

- aspects of authorities and responsibilities within the laboratory;
- a description of how the quality system operates;
- staff qualifications, experience, and training;
- documentation and document control;
- equipment operation and maintenance;
- calibration and measurement traceability;
- quality control;
- sample storage and handling;
- review of customer requirements;
- accommodation and environment within the laboratory;
- record keeping;
- dealing with complaints and anomalies;
- internal audits and reviews of the system; and
- corrective action.

Both QC and QA have their advocates and, in fact, it is recognized that the delivery of analytical data quality requires first that the laboratory has the capability to perform satisfactorily on the type of analysis under consideration and second that it was

actually doing so for the analysis in question. Accreditation mainly addresses the first of these requirements, the control of capability: it is an independent confirmation that the laboratory has the ability to provide quality data. Analytical QC addresses the second requirement.

The standards for QA systems all emphasize the importance of well-trained staff and in order to be able to demonstrate the laboratory's commitment to training to assessors, for the purposes of accreditation, adequate training records must be maintained. The standards also emphasize the importance of using documentation to avoid ambiguities and communication problems, and to ensure that all staff are trained and working to the same procedures.

A third essential of any quality system is that it must be subject to regular internal audits and that all nonconformances to the standard use must be corrected as soon as possible. Audits ensure that all the components of the system itself are monitored and that not only is the standard maintained but that the system is gradually improved. It is a truism that no quality system can be said to exist unless it incorporates auditing. These three features: training, documented procedures, and audits are vital for quality systems for all situations. They are not independent, of course, but interact. For example, the documentation of training requirements for many laboratory operations will preclude the need to repeat instructions for these operations in standard operating procedures. Also, in auditing, the auditors must be specially trained staff who are normally analysts, and they must perform their duties according to documented procedures.

The responsibility for the achievement and maintenance of analytical quality rests on all the staff at all levels in the organization, and it needs to be stressed that the first line of management, the section leader or supervisor in charge of practical analysis has a key role to play. The section leader continually witnesses and monitors staff performance and identifies training needs, arranges for training to be provided when required, ensures procedures are followed, calibration and standardization routines are observed, reagents and equipment are maintained, that calculation checks are made, and records are properly kept. These are the basic disciplines of a quality system and they can only be consistently followed when there is a high standard of supervision at the bench.

## Accreditation in the United Kingdom

Accreditation of a laboratory means the official assessment and certification of its quality system as meeting the requirements of such a standard.

Assessment of an analytical laboratory quality system may be made by the laboratory itself. It will have little or no value in the eyes of many customers, however, since it will be seen as a subjective and favorable assessment. However, internal audits and management reviews of the system, made as a requirement of a quality system standard, are self-assessments and are valuable, as explained in the previous section.

Accreditation, also known as registration or certification by some assessment bodies, may be second- or third-party. Second-party accreditation is made by the customer's own QA department either to their own in-house standard or to an independent standard such as ISO 9001.

An independent body, having no other commercial interest in the organization it accredits, conducts third-party accreditation. In the United Kingdom, a testing (or calibration) laboratory would be accredited to ISO 17025 by the United Kingdom Accreditation Service (UKAS).

Assessment of a testing laboratory to the ISO 17025 standard is conducted against a schedule, which is a matrix of sample types tested, determinants measured, and the methods used. The laboratory may perform a much wider range of tests than those for which it seeks accreditation, but these will not be included in the assessment. The assessment team will include experienced analysts to ensure that the latest or most appropriate methods of test are used, that method validation studies have been made and recorded, and that appropriate QC is being conducted, including participation in proficiency-testing schemes where available. They also ensure that instruments are used and calibrated to meet the demands of the test methods. Another peer review aspect is the witnessing by assessors of a selection of the tests from the schedule. The assessors also ensure, of course, that all the other requirements of ISO 17025 are met (Table 1).

Once a laboratory has implemented a quality system in accordance with these requirements, it must make a formal application to UKAS to have its system assessed for the purpose of accreditation and at this stage submits its Quality Manual and its proposed schedule of accreditation for examination, along with any other documentation requested by UKAS. The manual describes the policies and practices through which the laboratory addresses the requirements of the standard. Provided UKAS is reasonably satisfied with the documentation received, and once the laboratory has been advised of any areas needing further attention before assessment, the arrangements for the assessment visit are made. It takes the form of a major assessment/audit

**Table 1** Main features of the ISO 17025 standard

<i>Management requirements</i>

Assuring the quality of test and calibration results
Reporting the results

The processes of assessment and registration of a quality system to ISO 9000 standards or of assessment and certification of compliance with the GLP Regulations are similar.

and review of the quality system by the assessment team who, at the conclusion, will report that they will recommend to the UKAS Executive that accreditation be offered or will describe what further action must be taken by the laboratory to achieve the standard. Further formalities include an agreement on the contents of the schedule, which is issued by UKAS, and the laboratory making a written undertaking to comply with regulations concerned with the use of the UKAS logo. The process does not end here: the laboratory will be subject to a surveillance assessment after 6 months, and then annually, and after 4 years the whole process of full assessment must be repeated for reaccreditation.

For completeness, it should be mentioned that laboratories providing QC and analytical support to pharmaceutical production, and also to the production of medical devices and diagnostic materials, are subject to assessment to ensure they comply with the relevant requirements of the Guide to GMP. These requirements are very similar to those found in the other standards. The laboratories are not accredited, but compliance with requirements is a condition of granting and maintaining a manufacturing license for the products concerned.

Assessments for both GMP and GLP are made by staff from the Medicines and Healthcare products Regulatory Agency (MHRA).

## Accreditation in Other Countries

Within the European Community (EC) the breaking of trade barriers and the need to overcome various attitudes between nations that were once rivals or worse, has led, in the analytical community, to a great amount of interest in the application and harmonization of standards. Some nations are well ahead in these processes, one of which is the United Kingdom. Others less advanced in the adoption of quality systems are now making progress particularly as EC legislation has obliged the adoption of GMP in several fields and is now beginning to specify the use of ISO 17025.

Much progress has been made toward the mutual recognition of accreditation and UKAS now has many agreements with its counterparts in other European countries and also with some organizations outside Europe. There is a forum for the discussion of accreditation harmonization known as the Western European Laboratory Accreditation Co-operation (WELAC). Another collaborative organization for the resolution of problems of mutual interest in analytical chemistry throughout the whole of Europe, known as EURACHEM, has focused its attention to date mainly on matters of QA, and together these two bodies have published a very useful booklet giving specific guidance on accreditation, now available as a UKAS publication.

However, there is no doubt that there are different perceptions about QA even within the Western European countries. Some chemists hold strongly to the view that QA is best managed through quality systems and accreditation. Others are equally committed to having long and careful professional training combined with participation in proficiency schemes.

Accreditation has long been established in Australia and New Zealand using standards similar to ISO 17025, and many other countries have now set up or are in the process of setting up organizations working to similar standards and principles.

Second-party accreditation is used widely in the United States, with many major companies, such as Ford, and official bodies, such as the US Environmental Protection Agency (EPA) acting as key players. The best-known public sector QA requirements are those of the US Food and Drug Administration (FDA) for registration and compliance with GLP and GMP, and the EPA Contract Laboratory Program (CLP). The FDA requires manufacturers

and importers of medical products to register with them and comply with a GMP regulation, which the FDA has a legal obligation to inspect and enforce. The FDA GMP regulation was developed in accordance with the basic principles of QA, which have as their goal the production of articles that are fit for their intended uses. The GMP requirements are similar to those of other quality standards and the inspections are conducted along the same lines as other assessments, but in great depth, usually applied to all aspects of QA of one or a few products.

The EPA's Contract Laboratory Program was designed to support the EPA's 'Superfund' program by providing analytical data of a known and documented quality. The major objective of CLP is to provide access to a range of analytical services on a high volume cost-effective basis. The CLP uses a highly structured, inflexible approach to analytical procedures to provide legally admissible evidence for use in EPA enforcement efforts. Before a laboratory is awarded a contract, it must be evaluated and meet a number of QA requirements that are largely similar to those already described under UKAS assessment, and which include a satisfactory performance on a performance evaluation sample. When the contract has been awarded, the laboratory must undergo a number of postaward evaluations including surveillance inspections and periodic performance evaluation testing.

Third-party accreditation is now increasing in popularity. Some laboratories now have quality systems registered to ISO 9000 series standards, and third-party accreditation for laboratories based on ISO 17025 has now become widely used through the National Voluntary Laboratory Accreditation Program (NVLAP) administered by the National Institute of Standards and Technology and the A2LA scheme of the American Association for Laboratory Accreditation.

## The Future of Accreditation

Laboratory quality systems and related quality activities such as participation in proficiency-testing programs are being adopted increasingly. They have existed in the United Kingdom, certain other Western European nations, Canada, Australia, New Zealand, and the United States for many years. They are coming into increasing use in India and the Far East, South Africa, and Eastern Europe.

Commercial pressures and legislation are both certain to increase the requirement for third-party assessment and registration of laboratory QA arrangements, whether to ISO 17025, ISO 9000, GMP, or GLP.

The need for harmonization of standards, where it is considered necessary, and mutual recognition of registration and accreditation schemes, is of increasing concern and importance to trade. This will inevitably result in progress toward a unified system of recognition of competent laboratories. However, difficulties between major groups of trading nations, and different perceptions of analytical quality and how it is achieved and maintained, will act to delay the process. It is therefore unlikely that true international agreement will be realized for some years yet, although it must always be an objective to pursue. It might be that such agreement could be possible only if analytical chemists in all countries are trained to a common core syllabus, which includes a significant content of analytical QA principles.

## The Analytical Laboratory

### Role of an Analytical Laboratory

The role of an analytical laboratory within most organizations is to provide information upon which decisions can be made. A laboratory can be responsible for:

- process analysis of intermediates and bulk products;
- quality control of raw materials and/or finished products;
- research and development of new products.

The laboratory can be located within an industrial, medical, or academic environment, but regardless of the location, it still has the same overall responsibility. Therefore, it is crucial that as well as the need for information, the information must be produced in a timely manner with appropriate quality to allow effective decision-making.

While samples enter a laboratory where they are analyzed, it is rare for the information to be used there; the decision-makers usually reside outside of a laboratory. Therefore, a laboratory should integrate with its client departments to become an efficient part of an organization or enterprise. One element of this integration is to take the laboratory to the sample or process rather than the sample to the laboratory. When taking the laboratory to sample the analytical chemist can use conventional equipment or use some of the processes and techniques outlined in this article such as electronic noses and tongues, membranes, sensors of all descriptions, and continuous flow systems.

Regardless of the analytical system used, all it will do is to generate data. Other software applications will be needed to reduce the data to information and then to disseminate it to enable decisions to be taken.

### Need to Increase Productivity

Many laboratories are situated in industries that operate under regulatory guidelines, such as Good Manufacturing Practice (GMP) or Good Laboratory

The need for harmonization of standards, where it is considered necessary, and mutual recognition of registration and accreditation schemes, is of increasing concern and importance to trade. This will inevitably result in progress toward a unified system of recognition of competent laboratories. However, difficulties between major groups of trading nations, and different perceptions of analytical quality and how it is achieved and maintained, will act to delay the process. It is therefore unlikely that true international agreement will be realized for some years yet, although it must always be an objective to pursue. It might be that such agreement could be possible only if analytical chemists in all countries are trained to a common core syllabus, which includes a significant content of analytical QA principles.

## The Analytical Laboratory

### Role of an Analytical Laboratory

The role of an analytical laboratory within most organizations is to provide information upon which decisions can be made. A laboratory can be responsible for:

- process analysis of intermediates and bulk products;
- quality control of raw materials and/or finished products;
- research and development of new products.

The laboratory can be located within an industrial, medical, or academic environment, but regardless of the location, it still has the same overall responsibility. Therefore, it is crucial that as well as the need for information, the information must be produced in a timely manner with appropriate quality to allow effective decision-making.

While samples enter a laboratory where they are analyzed, it is rare for the information to be used there; the decision-makers usually reside outside of a laboratory. Therefore, a laboratory should integrate with its client departments to become an efficient part of an organization or enterprise. One element of this integration is to take the laboratory to the sample or process rather than the sample to the laboratory. When taking the laboratory to sample the analytical chemist can use conventional equipment or use some of the processes and techniques outlined in this article such as electronic noses and tongues, membranes, sensors of all descriptions, and continuous flow systems.

Regardless of the analytical system used, all it will do is to generate data. Other software applications will be needed to reduce the data to information and then to disseminate it to enable decisions to be taken.

### Need to Increase Productivity

Many laboratories are situated in industries that operate under regulatory guidelines, such as Good Manufacturing Practice (GMP) or Good Laboratory

Practice (GLP) in the pharmaceutical industry, or voluntary quality schemes such as ISO 17025. This can result in a growing number of samples for analysis with stricter control of administrative procedures as a means of ensuring quality. Other laboratories operate in companies and industries where there is a need to contain costs whilst maintaining analytical information to make decisions. To overcome these issues, laboratories need to increase productivity as a means of curtailing rising staff numbers and/or labor costs.

If productivity increases are sought, then there are two possible approaches. The first approach is to change the process and the accompanying procedures so that some tasks are simplified or even eliminated; as such this may not involve the use of automation. However, the viability of this approach is subject to question unless labor costs are reduced dramatically. Therefore, the second approach is to use laboratory automation.

### The Aims of Laboratory Automation

The use of automation within an organization is an opportunity to create strategic advantage, which is manifested in one or more of the following factors:

- Better decisions based on valid data. This can lead to research that is more effective, faster time to market for new products, or to better products that due to their quality can increase customer satisfaction and market share.
- Improved organizational productivity.
- Reduced risk to employees.

Bringing these aims down to an analytical laboratory level, the automation of a task should produce one or more of the following advantages that will contribute to the aims above:

- Greater increases in productivity (either in numbers of samples assayed per unit time or speedier turnaround time); resulting in overall cost reduction and increased productivity.
- Automated systems that should be capable of the same or better precision and accuracy as existing manual methods with improved quality and reliability of measurement.
- The freeing of trained laboratory staff to do more creative or productive work than tedious tasks thus improving morale.
- Reduced human contact with biological or chemical hazards.
- Lower the consumption of sample and/or reagents used in an automated analysis.

### Problems with Laboratory Automation

How well have laboratories fared in implementing systems in practice? From a historical perspective not very well, Betteridge has stated: "the development of automation in analytical chemistry can be viewed as a series of steps in which the solution of today's bottleneck creates another problem for the future to solve."

This was shown succinctly by the development of automation in analytical chemistry:

- Before the 1960s, the barrier to automation was actually generating the data; the solution was the development of electronic control of apparatus. When apparatus was controlled, the new problem became the large amounts of chart paper produced.
- Therefore, in the 1960s the problem became data acquisition; this was solved by digitizers, which acquired the data but produced a new problem of manipulation.
- This was solved in the 1970s with the introduction of minicomputers to reduce the data; but many computers created the problem of data transfer.
- Data management was solved in the 1980s by the use of workstations and a laboratory information management systems (LIMS) but the problem moved to become the management of technical data.
- The interpretation of these data either by expert systems or artificial intelligence is the current problem for the 1990s to solve.
- The integration of the different data systems and LIMS to design the paperless laboratory is the task of the first decade of twenty-first century.

Part of the historical problem was the lack of technology or instrumentation at the various times discussed to allow an all-encompassing solution. The other part of the problem was, and still is, the lack of vision of many chemists to see a laboratory as an integral part of an organization.

## Laboratory Information Management Systems

### What is a LIMS?

The major function of most analytical laboratories is the creation and presentation of information quickly to make decisions. A LIMS is one of the major laboratory automation tools at the disposal of analytical chemists to help achieve this aim. Although a LIMS does not undertake analysis, a LIMS can be pivotal in integrating both the laboratory operations and the laboratory itself within an efficient organization. A LIMS can provide a laboratory with the means to

automate the processes of information creation and presentation, as well as being the platform for information dissemination to clients and senior management.

However, this is not always the case. A large number of systems failed to meet initial expectations that implied that LIMS are not fully understood. To help overcome this, a LIMS model was proposed that enabled the requirements of a system to be visualized conceptually. It has been adopted, modified, and used as the basis of the LIMS concept model in the ASTM LIMS guide. However, the LIMS model focuses on identifying and visualizing the user functions within the laboratory environment and less on the strategic positioning of a system.

To overcome this problem, a paper by McDowall proposed a matrix for the development of a LIMS with a strategic focus. It introduced the concept of an operational, logistic, and strategic LIMS. The matrix is formed by plotting these three types of LIMS versus the scope of laboratory and organizational tasks that can be undertaken by such a system.

### A LIMS has Two Targets

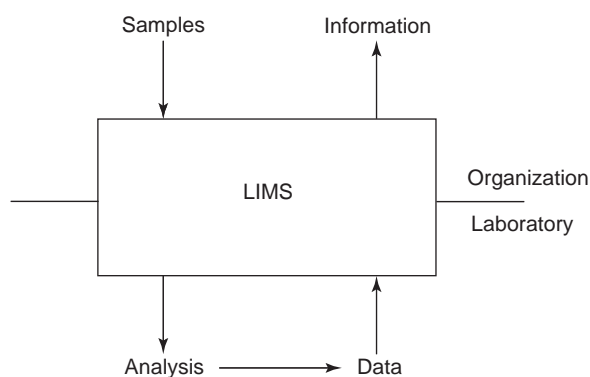

A LIMS is unlike any other piece of laboratory automation equipment available to the analytical chemist. It can provide benefits both within the laboratory and outside it. Thus, a LIMS has two targets:

- the laboratory: the information generator and
- the organization: the information user.

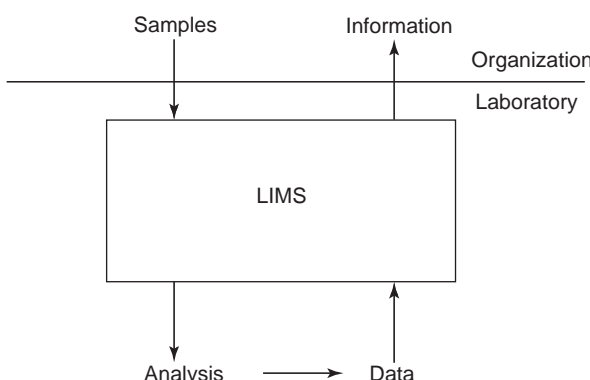

The problem is how to site and implement a system so that it hits both targets effectively.

Figure 1 shows an outline of the functions that a LIMS should undertake; the diagram shows a LIMS sited at the interface between a laboratory and an organization. Samples are generated in the organization and logged into the LIMS, the samples are analyzed within the laboratory, and data are produced and reduced within the LIMS environment to information that is transmitted back into the organization. Figure 1 represents the ideal setting of the LIMS: both the organization and the laboratory benefit. The line dividing the organization and the laboratory show the system is of equal benefit to both.

However, there are two other implementations that are possible with a LIMS, which result in different position of the interface between the laboratory and organization. Figure 2 shows the more common implementation, which is probably typical of the majority of early implementations of LIMS in the 1980s. The main functions carried out by the system are the same as that discussed previously but the emphasis of the implementation is different. The

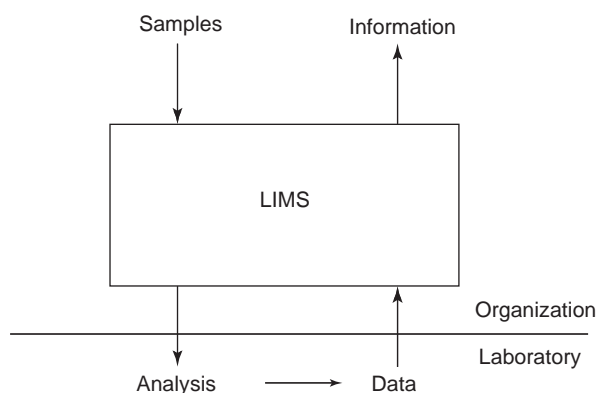

**Figure 1** Ideal implementation of a LIMS. The interface between the laboratory and the organization shows that the LIMS benefits both.

**Figure 2** A bottom-up implementation of a LIMS. The laboratory benefits but the organization does not.

boundary between the organization and the laboratory has been moved up and the benefit of the LIMS is almost exclusively that of the laboratory with little payback for the organization. Here, the LIMS is a toy for the laboratory that few others are allowed to play with. The system is built from the bottom up but with no consideration for anyone outside of the laboratory.

The rarest alternative implementation is presented in Figure 3. This is the top-down approach, where senior management or, worse, the information technology group has decided that a LIMS will be implemented. There has been little consideration for the laboratory, only the organization. The analysis and data gathering functions of a LIMS have been ignored, which allows the staff the latitude and the excuse to develop their own alternative local processing solutions. This system requires additional work by the staff to ensure its success in addition to the normal analytical function. The likelihood of failure with such a system is much higher than with the other two forms of implementation.

**Figure 3** A top-down implementation of a LIMS. The emphasis is on the overall system benefiting the organization but the implementation allows the laboratory to develop data analysis solutions independently of the LIMS.

As can be seen when comparing the three alternatives, there is a balance to be found between the needs of the organization and the laboratory. The interface between the two must be carefully defined; however, the initial implementation should be toward the analytical laboratory, the information generator. Automating the information generator is the key to success for the whole LIMS.

The importance of the LIMS matrix, described in the following section, allows that dividing line to be drawn accurately before starting the project and manage the implementation of a system.

### Construction of the LIMS Matrix

The matrix axes consist of LIMS type plotted against function in the laboratory or organization. Each will be outlined below.

**Three types of LIMS** There are three types of LIMS: operational LIMS, logistic LIMS, and strategic LIMS. The functions and aims of these systems are described in more detail.

**Operational LIMS** This is a basic system that automates analytical processes in the laboratory. This system increases the efficiency of a laboratory but the impact is only local. A computer system in this category would normally be concerned with the operation control of a laboratory and would automate functions such as sample entry, work list generation, and report preparation. Another way of looking at this system is usually the automation of the status quo. Such a system is probably typified in **Figure 2**.

**Logistic LIMS** In addition to the functions of an operational LIMS, a logistic LIMS provides users,

especially managers, with the information necessary to undertake their work. Such systems generate control information. Ultimately, this information improves the effectiveness of a laboratory.

**Strategic LIMS** The aims of a strategic LIMS are to integrate information and applications from different functional areas. From this information it may be possible to reshape operations. A strategic LIMS has the greatest impact upon the business by increasing the competitiveness of the laboratory.

Properly designed, a logistic or strategic LIMS will achieve the correct balance shown in **Figure 1**. However, too great an emphasis at the start of the project is likely to produce the system shown in **Figure 3**.

**The system scope** Where does a laboratory begin and end? Clear definition of these two points helps to determine the scope of a LIMS. The six areas of system scope that define the matrix are laboratory operations, monitor and control of operations, laboratory management, reporting and communications, analytical decision-making, and organizational integration. This is the maximum scope of a LIMS. These comprise the horizontal axis of the matrix. The function carried out by each of these areas is outlined in **Table 1**.

**Matrix Construction** The matrix can now be formed as a three by six block and is depicted in **Figure 4**. There is a division between the first three items of the system scope. Laboratory operation, monitor and control, and laboratory management are concerned with functions inside the laboratory. Organizational functions are represented as reporting and communications, analytical decision-making, and organizational integration.

The individual components of the matrix are shown in **Figure 5**; this is an outline of the functions of a LIMS within each cell.

Considering all of the functions in **Table 2**, one can see that the main functions of the laboratory are outlined in the lowest three cells of the matrix (operational LIMS: laboratory operations, monitor and control, and laboratory management). This represents the basic laboratory operation and is indicative of the data domain discussed previously. This is shown in **Figure 5** as the box labeled 'Laboratory'. Ideally, the major impact of any computer system, including a LIMS, should be strategic. The organization uses the information generated by the analytical laboratory and this can be considered as the information domain. The maximum impact of a LIMS is in the top right hand side of the matrix.

**Table 1** Functional scope of a LIMS

Functional area	Scope
Laboratory operations (LO)	<ul style="list-style-type: none"> <li>To automate and structure work</li> <li>The automation of the basic laboratory operations such as sample entry, work list generation, and results entry</li> <li>Work rationalization</li> </ul>
Monitor and control (MC)	<ul style="list-style-type: none"> <li>To evaluate performance</li> <li>The monitor and control of the laboratory operations by such processes as approving results, the use of quality control schemes, and the checking of transcription errors</li> <li>Provide standards, measures, and information for performance evaluation and feedback</li> </ul>
Laboratory management (LM)	<ul style="list-style-type: none"> <li>Support intellectual processes</li> <li>Organizing and managing the laboratory functions and operations</li> <li>Project and work planning</li> </ul>
Reporting and communications (RC)	<ul style="list-style-type: none"> <li>To augment human communication</li> <li>Here are the means to transmit results or reports and communicate with the clients of the laboratory</li> </ul>
Analytical decision-making (AD)	<ul style="list-style-type: none"> <li>To aid and speedup decision-making</li> <li>Providing quality information in a timely manner and the right format to make decisions</li> <li>Supporting processes in production, development, or research</li> </ul>
Organizational integration (OI)	<ul style="list-style-type: none"> <li>Facilitate intra and interorganization transactions</li> <li>Integrating with other functional groups in the corporation and between organizations</li> </ul>

**Figure 4** An outline of the LIMS matrix. S-LIMS, L-LIMS and O-LIMS are strategic, logistic, and operational versions of LIMS, respectively. The horizontal axis functions are laboratory operations (LO), monitor and control (MC), laboratory operations (LM), reporting and communications (RC), analytical decision-making (AD), and organizational integration (OI).**Figure 5** The LIMS matrix illustrating how some LIMS are implemented with the emphasis on laboratories and the overall business objectives where the best payback on the system investment would be obtained.

It consists of the strategic LIMS cells of results and communications, analytical decision-making, and organizational integration, and is marked 'Business Objectives' in **Figure 5**. It should be the aim of every LIMS to aim for the top right hand area of the matrix.

However, it should be stressed that not every LIMS will be developed to the full extent of the matrix. There will, inevitably, be some duplication with other computer applications that have been implemented or are being implemented within an organization. The aim, therefore, is to develop the matrix

around business objectives and a good financial justification to make the system pay for itself in a reasonable time period. One way to do this, and make the economical use of resources, is to link the implementation of the LIMS with existing applications to provide the functionality described in the matrix. Here, the LIMS was linked through a communications network to a document management software package that can be itself developed to produce computer assisted new drug applications (CANDAs) that will fulfill the requirements of the matrix.

**Table 2** The LIMS matrix

<i>Strategic LIMS</i>	Integrate with client operations	Compare requests with capacity	Resources based on workload	Integrate with document management software	Decision support system integration	EDI & CANDA Rapid commercialization
<i>Logistic LIMS</i>	Integrate laboratory operations	Automate regulatory compliance	Monitor test use	Electronic reports to clients	Highlight out-of-specification results	Remote online inquiry
<i>Operational LIMS</i>	Automate existing operations	Monitor and approve results	Sample status Billing	Paper reports to clients	Display results versus specification	Remote printing of results

### LIMS Matrix Views

Similar to the ability to use views to gain an insight into the contents of a database, the same concept can be used to gain an insight into the matrix and its impact. We will consider two main views in this section. The first is the vertical view through laboratory operations and a horizontal view across the logistic LIMS cells.

**Vertical view of laboratory operations** The vertical view through the laboratory operations cells of the matrix will see how this changes from the operational LIMS to the strategic LIMS. The lowest left hand cell of the matrix represents the core of the analytical laboratory; the inventory of assay methods and instrumental techniques. The operational LIMS would generally automate these processes and techniques. Business rules would be incorporated into the system such as who was allowed to create, modify, or delete methods within the LIMS, how many replicates were needed for each analysis. Samples would be logged in and work sheets would be produced for each analytical run. All functions are the usual LIMS functions within the analytical laboratory.

At the logistic LIMS level, the matrix is looking for integration of laboratory operations. This would be the linking of analytical instruments to the LIMS for electronic transfer of results, samples would be bar coded and would have their location monitored as they move through the laboratory. The various applications used for analyzing data and producing results would be integrated into the LIMS environment and would not be standalone applications requiring reentry of data.

At the strategic LIMS, the system should be integrating with client operations. Possible examples of this could be the clients logging onto the system to initiate sampling within their areas. The system would print bar coded labels for the samples from printers within the client's area. The samples would be submitted to the laboratory for analysis and logged into the system via the bar code. An alternative scenario, in a production environment, could be the analytical laboratory developing robust methods for the production staff to operate and use the LIMS as a means of collating and disseminating the results. The LIMS would be the medium for the laboratory staff to monitor the performance of the analytical methods and alert them if a method were getting out of control.

**Horizontal view of a logistic LIMS** Looking along the matrix cells at the logistic LIMS level would give us a view of a system that has integrated laboratory

operations as described above. The monitor and control cell requires automated regulatory compliance, which would also include compliance with a quality scheme such as ISO 9000. There would be audit trail facilities as standard and the establishment of chain of custody from the time the sample arrived into the laboratory to when it was disposed or returned to the client. Automated regulatory compliance is a term that means that the documentation required to meet the quality standards that the organization is working to is generated by the system automatically. This would include receipt of samples and documentation of exceptions.

Laboratory management is concerned at this level with monitoring test use. Many laboratories accept requests for sample assays without questioning the rationale for the analysis or finding out if the information generated is ever used. The purpose of this cell is to question the analyses requested and monitor how the results are used. Is the laboratory generating the right information and offering the methods that the clients want? It is managing the client as much as managing the future direction of the laboratory with anticipating the services it will offer. The information from the LIMS, via a retrospective search of the database, will allow managers to follow up work that was done and how the results were used. Depending on the implementation of the whole system, this could be done electronically via feedback loops or manually.

The cells of reporting and communications, analytical decision-making, and organizational integration cover the functions whereby reports generated by the system are transmitted via the network, out-of-specification results are highlighted, and the clients can have remote access for online query of the database. The aim of these first two cells is to transmit the report to the client effectively and highlight aberrant results; this allows the client to focus immediately on problem areas. Some of the options available to implement this section are covered in more detail under 'Financial justification and risk assessment' in the next section.

These views of through the matrix are based on straight lines. However, not all systems will implement in straight lines and the views of individual systems will be based on functions required by an organization and a laboratory.

**Using the matrix for financial justification and risk assessment** The matrix can be used to justify the money spent on a LIMS on a cell by cell basis. The costs for each cell in the matrix can be calculated and the benefits quantified. This cost justification can be used to justify each cell of the matrix to senior

**Figure 6** The LIMS matrix showing increasing risk and benefits the further the system is implemented outside of the laboratory.

management. It will enhance the efficient use of resources and avoid duplication of functions within an organization. However, this idea can be taken further. Figure 6 shows as the LIMS is developed out of the operational level to the logistic and strategic levels and also into the organization there is increasing benefit but there is also a corresponding increase in the risk of the project. Therefore, a combined cost justification and risk assessment can be made for each matrix cell.

Let us look at two examples of this approach. In the logistic LIMS level of the matrix corresponding to the organization, communication is electronic, there is the ability to highlight out-of-specification results for the client for decision-making, and to help organizational integration, clients can access their results remotely. Ideally, the first two functions will help communicate results to the clients and enable them to make effective decisions. The third will enable the client to access the LIMS to see the progress of their samples and avoid the need to phone the laboratory to enquire about progress. All functions are desirable to integrate the laboratory and the organization. However, senior management is looking for a cost-benefit justification and an outline of the risks involved. Imagine two companies, one where information technology is well established and the second where use is not as successful as management would wish.

Scenario one would envisage an organization with an existing network linking all functional groups. This is a key component for organizational integration and provides the medium to move information. This organization is relatively sophisticated in its use of information technology with e-mail and online diaries available and used regularly. The main communications component, the network, is already installed. Therefore, the cost-benefit justification will only require expenditure for the customization of

reports and the linkage of the LIMS with the e-mail system to transmit a report to the client, a relatively minor cost component. To highlight out-of-specification results, more programming would be required to place an asterisk to highlight an out-of-specification result. The final cell in this level of the matrix requires external read only access via the network to the LIMS database. Security levels would be set up within the LIMS to prevent unauthorized users from changing results and roaming around the database; this may require a customized database view for each client or client group. With a network in place and working, the approach to implementation might be to authorize the communication cell and the organizational cell to proceed, with the ability to highlight out-of-specification results being implemented in the first place with the asterisk option. The risk assessment would be based upon a number of factors but would be low. The reasons are that there should be little impact on the ways of working as the staff already tend to work using the network facilities. The use of the matrix builds on the use of information technology and requires relatively little capital investment to be made.

In contrast, scenario two envisages an organization where information technology implementation is not always successful. A network is not in place throughout the organization and requires investment. Here the cost-benefit justification and risk assessment are changed dramatically to implement exactly the same functions. A higher capital investment is required to put in place the network. There may be the need to retrain or hire staff to run the network. Users would need to change their ways of working to use the system effectively, thus increasing the risk to the success of the whole project. Here the prudent approach would be to implement an operational level of the LIMS matrix: hard copy reporting first and concentrate on getting the LIMS working within the laboratory. As a future phase of the project, a network investment to the client groups could be justified on a piece by piece basis.

This illustrates the combined use of cost justification and risk assessment that should be applied to the use of the matrix. It also requires an assessment to be made of the use of information technology and the maturity of staff within an organization.

### Organizational Integration and LIMS

The use of information technology crosses functional boundaries: robots and other automation equipment are justified and used locally; however, the impact of a LIMS is far greater as shown by the matrix.

A LIMS has the ability to influence groups outside of the laboratory.

An operational LIMS has its impact mainly within the laboratory with little influence in the rest of the organization. As discussed earlier in this article, this is the typical implementation seen in the 1980s. The logistic LIMS has its main impact on the functional groups that work closely with the laboratory. They are linked via a corporate network that is fully realized with the strategic LIMS. The strategic LIMS has its greatest impact on the organization as well as providing benefits to the laboratory and the client groups served by the laboratory.

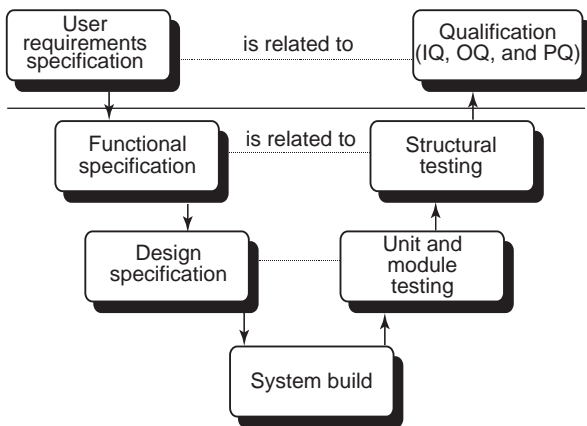

The implementation of a LIMS with increasing logistic and strategic elements means that there will be greater impact on the organizational structure. In instances where this occurs, a question arises: which processes should be automated?

Most LIMSs automate the current ways of working. These have evolved over time, but may not be efficient or cost-effective. Examples may be the way samples are received by the laboratory via multiple logbooks or several signatures are required to authorize a report. It may be prudent when considering such a system to consider reengineering or redesign of the laboratory operations prior to automating them. This is a higher risk approach, but it can improve the overall efficiency of the laboratory and its client groups and may be better than simply automating the status quo. We shall explore this approach in the next section of this module.

The other element in the equation is the impact of the LIMS on the existing organizational structures. It may be that organizational changes are required when implementing either a strategic or logistic LIMS. If this has not been anticipated or thought out, this can make this a high-risk factor. To avoid project failure due to this cause, an assessment of the impact of the system on the existing organizational structures is essential.

### LIMS and the System Development Life Cycle

The development and implementation of an information system such as a LIMS follows the traditional system development life cycle (SDLC) shown in Figure 7. Normally, equipment is purchased off-the-shelf and used with little or no modification; however, a different approach is necessary with complex laboratory automation such as a robotic system or a LIMS. In this instance, the users must state what tasks they want the system to undertake. Often this places the chemist in a difficult position as he or she

**Figure 7** Systems development life cycle.

is not certain what the system should or is capable of doing.

### Quality and the SDLC

Quality is designed into a computer application by defining the requirements and functions of the system. Quality can never be tested into a LIMS. Quality of a system is manifested in different ways such as user friendliness, undertaking the task it was designed to do, robustness of operation, and tolerance of error. During the development of the system by the supplier, quality is incorporated by ensuring that design and programming standards are adhered to. Furthermore, there are testing procedures that can be undertaken by the supplier to test the system prior to its release.

### Life Cycle Approach to LIMS Implementation

As can be seen, there are many stages to go through before the system is fully operational, thus the acquisition of a LIMS must not be undertaken lightly. The stages outlined in this module are guidelines, which based on the author's experience and can be recommended to any individual or organization contemplating an information system. These guidelines can be tailored or modified, as appropriate, to an individual situation.

As the life cycle unfolds the reasons for following this route will become apparent. The requirements and functions of a system must be fully defined, the responsibilities clearly stated, and good communications set up between all relevant parties. This is particularly important when the timescales of the SDLC are considered, the minimum overall time of a project is ~12–18 months and the maximum should be 24–36 months. However, timescales can be longer if the project is poorly managed. The timescales

obviously depend on the complexity of the project and how much configuration (changes of preset parameters in the software) or customization (programming) is involved as well how much time and resource can be committed by the organization. Configuration is preferable to customization for speed for implementation and long-term support issues.

The challenge for any organization is to implement a LIMS that supports the effective automation of 'information' production and distribution from the laboratory. Here the LIMS matrix can provide a high-level outline of what functions the LIMS should automate. Once the outline of the LIMS and the functions in the organization that it should automate has been discussed and agreed, the project proposal should be prepared.

### Project Proposal

The first stage in the life cycle is usually the preparation of a project proposal that will be reviewed by either senior management or a central computing resources committee. The information gathered during the laboratory review for the development of the laboratory strategy should be sufficient to state if computerization is a viable and cost-effective solution. Note the use of word 'computerization' and not LIMS, as the project proposal should be kept deliberately vague and not recommend definite hardware or software solutions.

The proposal document should contain an overview of the department and the problems that the system should overcome. It is important that the justification must be based on the business objectives of the department concerned and is not to be installed at the whim of management or an enthusiast. The outline justification must include the areas and estimates of cost savings that will be made when the new system is operational compared with an estimated cost of the package.

Outline approval by senior management to the often considerable financial outlay will be dependent on the ability of the laboratory to demonstrate, and where possible quantify, a return on the investment arising from benefits in:

- increased efficiency and productivity;
- reduced or limited increase in staff levels in relation to increased workload;
- increased scientific standards;
- production of more reliable data;
- improved speed of report production; and
- provision of management analysis functions.

The justification of a LIMS must be balanced between the 'tangible' benefits (i.e., those where a

return on investment can be calculated) and the 'intangible' benefits (i.e., where this cannot be done such as quality of data).

There is a balance between over-justifying the system to obtain project approval and being realistic about what the system will actually deliver in practice. This is very difficult to delineate; however, the review of the laboratory should give management the information to decide if the LIMS is worthwhile, if it is not, the project should not proceed.

A postimplementation review of the project, ~6–9 months after the LIMS is operational should temper overoptimistic justification of the system. The setting of criteria for success early in the project's life will help to make this review more objective than subjective.

Approval of the project proposal will normally allow the formation of a project team and allow the project to proceed to defining the requirements of the system, inviting tenders, and evaluating alternative systems.

### **The LIMS Project Team**

To solve the challenges posed by the design, implementation, and operation of LIMS a multidisciplinary approach is required. The formation of a LIMS project team to oversee all of the remaining stages of the SDLC up to the operation of the system is the normal solution. The minimum membership of the team will be users representatives (a vital component and often overlooked in some projects), laboratory management, and computing professionals.

There may be other members on the team such as personnel from client departments. When the system is to be operated under regulatory agency or government guidelines the involvement of a member of the quality assurance unit in all stages will be of direct benefit to the project. The project environment will entail computing and analytical experts working closely together; therefore, it is vital that each group has a full understanding of each other's areas of expertise and working practices. The computer scientist must know how the analyst works and vice versa, one area in particular must be the development of a common vocabulary for efficient and unambiguous communication between both parties.

A major problem in the implementation of any computer application, including LIMS, has been the crossing of disciplinary boundaries. The LIMS matrix can be used to help attain this goal: by giving both groups the common concepts and vision of a LIMS to help each group communicate with each other. Each discipline's own perspectives and strengths will be fused together in a project team

with the remit to implement a system successfully will enhance this communication.

The leader of the project team must be a member of the laboratory management, which clearly demonstrates to the users that it will be their system and not something that the computer department has decided may be suitable.

The project team must operate in a matrix management style, its members being responsible for what tasks should be undertaken and when they should be started and completed. The members liaise with their respective line managers who are responsible for providing the resources for the tasks and deciding how they should be carried out. This means that the project extends across department and discipline boundaries; therefore, communication is essential to ensure that members of the team and their respective line managers are aware of the progress and problems of the project.

### **User Requirements Specification and System Selection**

This is the most critical part of the system life cycle as it is the basis of all decisions and actions taken in the later phases. If a stage is wrong, then the rest of the life cycle can be jeopardized.

The assumption made in this section is that a commercial system will be selected rather than the organization changes their ways of working. A commercial system is a viable and cost-effective option as many systems are now available. Applications are networked and are scalable from small to large laboratories and can run from a single server across several sites and even continents.

The commercial approach has the advantage that development costs are shared over the whole user base and because of user feedback and competition there is continuous development of the software. A potential drawback may be that the vendor's conception of a laboratory may not be the way the package works and some configuration or customization of the package may be necessary.

**Understand the overall process** To obtain the best from the implementation of a LIMS, the project team will need to map and understand the whole process from sample generation to decision-making using the information generated. Inevitably, this will involve crossing functional boundaries and defining the hand-offs between the different departments involved in the process.

The team will need to identify where the process can be improved or redesigned to overcome bottlenecks in the existing process. As change is involved

with a LIMS project, the project team needs to give serious thought to changing the laboratory process to fit with the selected LIMS system. This will make the whole implementation faster than changing the LIMS to fit the existing laboratory processes.

**Write the user requirements specification** The new process map of the workflow gives the project team members the information needed to write the next document in the life cycle of a LIMS. This is the user requirements specification (URS). The URS is important as it gives the project team the outline tasks that the system should be capable of undertaking. In some respects, it can be regarded as a 'wish list' of functions that the system should be capable of performing.

The document should be written in a nontechnical style and follow a logical sequence starting from the entry of the sample into the laboratory, via analysis, through to the compilation of the analytical report and its distribution.

Each of the requirements needs to be uniquely referenced and be worded so that it can be tested. The URS is important as it defines what the laboratory wants from the system and stops the users being influenced by technology: the URS is the basis for the system selection.

**Write the invitation to tender** The URS is then converted into an invitation to tender or a request for proposal by appending to the document:

- A laboratory overview – describing the laboratory environment and the work undertaken. The analytical instrumentation and level of automation, the sources of work, and how results are reported. The present and past workload of the laboratory.
- Future of the laboratory – the future developments in automation, instrumentation, and techniques anticipated to be used by the laboratory. Estimated trends in workload and staffing. How is the laboratory changing?
- Integration with existing packages – data input from and output to other computers, software packages, and e-mail systems.
- Computing environment – describe the preferred hardware and software systems used at the local and corporate levels.

This information enables a prospective supplier to respond effectively to the invitation to tender. At this stage, for the project team to have as much choice as possible, the document should be sent to as many vendors as can be found.

To elicit similarly structured replies from all the vendors, either a section can be inserted in the tender document instructing the vendor how to respond or a checklist containing all the relevant questions that should be answered can be enclosed. It is important to know whether a function is available as standard in the package, needs to be configured within the standard package, customized, or is not available in the current released version of the system.

**Evaluation of prospective systems** The evaluation process is vital as it matches the laboratory requirements with those on offer from the suppliers. Unlike many other types of laboratory automation the full benefit from a system should not be expected until several months after the system has been introduced into the laboratory. This time lag means the impact of a wrong decision is much greater because much time, effort, and money have been expended. Therefore, the need to make the right decision the first time is very important.

The importance of requirements specification is now realized as it provides the written definition for the evaluation exercise. The key approach to evaluation is to develop an evaluation checklist for comparison of systems: the users should grade each requirement as either 'mandatory' or 'desirable'. All those features falling into the 'essential' category form the minimum requirements of the LIMS and the 'desirable' category features are those that are useful to have but the users do not require them in order to perform their normal role. To aid objectivity, essential items can be given a numeric value this will give a 'total score' for each system on offer.

The replies by suppliers to the tender document can be compared on paper to reject those obviously unsuitable, which should reduce the list to about four or five. These remaining should be visited and their replies discussed in depth and the systems evaluated by use. At the end of this phase, the systems may be reduced further to one or two for in-depth evaluation.

It should be noted that the sole use of a checklist should be discouraged as the subjective comments of the project team and users should be taken into consideration. This may take the form of comments on the interaction with the software or performance of the system.

Once a single system has been chosen, it should be tested in-house for up to a month (dependent on the complexity of the tasks it should undertake) to confirm that it is a suitable choice. Here the opportunity for all users to have hands-on access to the system must be encouraged. This in-house testing will usually entail the purchase of the license of a specified time from the LIMS vendor. If the evaluation is

successful, then the cost of the license should be deducted from the total cost of the system. If, however, the evaluation shows that the selected system is unsuitable then little time and money has been lost, which now means that the project team must reevaluate their requirements and consider other vendors and approaches and decide how to proceed with the project.

A final point for the evaluation: the project team must consider the laboratory environment whether it is changing or static. The reason is that software handles routine tasks well, but it is the unusual request that will prevent easy operation. Therefore, in a changing laboratory will the software be able to cope with changes in working practices?

This formal approach to the definition and evaluation of a LIMS will enable the project team to proceed to the purchase of a system with the confidence that it will undertake the tasks required of it. The in-house evaluation of the system will highlight areas that require tailoring to the way the laboratory wishes to operate as well as finding the deficiencies where custom software will be needed for full functionality.

**Vendor audit** In Figure 7, a line is drawn under the URS and the qualification stages of the V model. The reason is that for a commercial system, all the stages under the line are the responsibility of the vendor and one should see if the system offered is suitable in one's laboratory. In regulated laboratories such as in the pharmaceutical industry, there will be a requirement to see if the application software were developed in a quality manner. Hence, the need for a vendor audit.

**Purchase of the selected LIMS** The purchase of a LIMS will usually follow a company's procedures for capital equipment authorization, as the cost of a system will usually exceed the minimum limit for this process. The exception may be the instance when a company is purchasing the software alone to run on an existing processor and the cost may be considered as a revenue item.

Before placing an order, it is vital to check:

- Sufficient peripheral devices such as terminals, plotters, and printers are available to use the LIMS. This should ensure that there would be no complaints by users being unable to access the system.
- The small print of the contract should be examined to ensure that there are no escape clauses that can allow the vendor to avoid doing what they have promised to do.

- Ensure that commitments to enhance or modify the system are put in writing to protect both the purchaser and the vendor from any misunderstandings that might occur.

The purchase procedure will generally entail writing a further document, the basis for which is the project proposal. For most systems this will entail abstracting and updating the information already gathered. Include in the justification:

- business objectives of the laboratory;
- problems of the existing method of working;
- objectives of the system and how it should overcome the existing problems;
- design of the proposed system;
- detailed costing of the system including support, consultancy, and internal resources;
- competitive quotes from other suppliers, if required; and
- costs for laying information technology infrastructure and other equipment if required.

Once the purchase has been authorized and the order placed with the vendor, planning of the implementation should begin in conjunction with the vendor.

### Functional Specification

Once the final system has been chosen, the URS is used as a basis to input into the next document the functional specification that is the record of the configuration or customization of the application.

What is the difference between the requirements and functional specifications? An example of this could be a program to update records within the database of the LIMS. In the URS all that would be mentioned would be the need for a program to update records in the database. In contrast, the functional specification requires more detail:

- Functions that the program should undertake: create, copy, modify, view, and print records.
- Security considerations: who should have access to which functions, e.g., new or basic users may only use the view and print functions.
- Screen lay outs: how the program should appear to the user.
- Program logic: operation of the software if the module is to be customized or programmed.

As can be seen there is much more information required in a functional specification; it is for that reason that the configuration of a LIMS is faster and far more preferable than customization. It is also

easier to omit details, often essential, such as a 'delete record' function from the specification. This is the cause of many problems and one main reason for enhancement of the system functions later in the SDLC. An apocryphal definition of enhancement is 'what we forgot the first time around'. At first reading, it is funny; unfortunately it is also true.

Essentially, the functional specification is a document that can be read by the users and therefore is written with the minimum use of computer terminology. The functions to be undertaken by the system must be stated in a clear and concise manner. A major problem, if the wording is ambiguous or does not adequately describe the function, can be misinterpretation by programmers resulting in the program not working as required (see above). Close liaison between chemists and the supplier is essential, as the main problem is the crossing of disciplinary boundaries. The systems analyst who is drawing up the specification document must be aware of the intimate workings of the environment where the LIMS is targeted. To this end, spend one or more days walking him or her through the laboratory and show the operation. Great care is needed to include all working practices into the document to ensure that flexible software is written. Remember to define words to ensure common understanding.

Mistakes are expensive to correct and will cost time, effort, and credibility. The best advice is to consult the users, the laboratory management, and the client departments concerning the content of this document.

### **Qualification of the System**

There are three stages of this process:

- Installation qualification (IQ): is the system installed correctly.
- Operational qualification (OQ): does the system operate as the vendor says it should.
- Performance qualification (PQ): does the system work the way the users want it to.

The IQ and OQ can be performed in a relatively short time scale but there is usually a delay in undertaking the PQ as the system needs to be configured or customized before the testing can be started.

**Installation qualification** Prior to purchase of the LIMS, consideration should be given to the setting of the various pieces of hardware and to any special requirements for those areas. The LIMS computer could be sited in a central computer room that is air-conditioned room to control humidity and

temperature and with a false floor to allow for the large number of cables needed to connect the analytical instruments and peripheral devices to the processor. To allow controlled shutdown of the system in case of a power failure an uninterruptible power supply should be considered. The room housing the computer may need to be secure with access limited to authorized personnel only. The placement of the peripheral devices and the associated cables requires detailed discussion and planning with the computer department.

The system software and components will be delivered and installed, usually by the vendor's staff and any tests undertaken documented by them.

**Operational qualification** The OQ may be followed immediately from the IQ and can be performed by the vendor's staff or trained laboratory staff. This phase of the life cycle can be very short if there is extensive alteration of the system or relatively long if the system is used with little or no configuration.

**Performance qualification** PQ, also known as acceptance testing, has the objectives of confirming that the system operates as expected and to find errors in the LIMS.

It must be stated at the outset that the end user is responsible for PQ of the LIMS. However, it is impractical and virtually impossible to find all the errors in a system because of the multitude of different pathways through the software and the time it would take to test them all. Therefore, the PQ tends to be a compromise as software bugs will be found after the system becomes operational.

The size of most commercial LIMS is such that the PQ testing will be focused on the key system functions that acquire data, store it, transform it, and report it. If the system has been customized then the customized functions must also be tested as these are unique.

### **User Training and Roll-Out Strategies**

Once the LIMS has been validated and the documentation is available, the users can be exposed to the new system. There are three main ways this can be accomplished:

- total immersion,
- parallel operation, and
- selected use.

One approach to consider is a trial operation of the system, before the validation and the documentation of the system are finished, to find the working practices that will be used after the system becomes

operational. Regardless of which method is chosen, the learning curve is usually long, requiring much training and understanding. However, the benefits of a well-designed system should always outweigh the time spent on training.

**Total immersion** An implementation using total immersion uses the LIMS from a set date and abandons the old method of operation. This is a bold form of implementation and requires total confidence in the system that has been gained during both the acceptance testing and validation stages as well as total commitment from the users and management. This style of implementation is best suited when the LIMS is being used to implement change in the laboratory and its operation differs radically to the existing ways of working.

**Parallel operation** Parallel operation involves the running of both the old and new systems together to allow time to cross-check the data and information produced by the two methods and to build confidence in the LIMS. This approach will be applicable where tasks undertaken by both systems are similar; however, if the data produced by the two methods are not the same then the reason must be found and the problem resolved. If there are problems with the LIMS then the old system can still be used to produce results whilst a remedy is sought. This approach to implementation is resource intensive and a deadline should be given after which only the LIMS will be used.

**Selective use** Selective use, as the name implies, is the teaching of a small number of users how to use the LIMS. This is a cautious approach but has the advantage of allowing prompt attention to problems almost as they arise; moreover, in cases of slow learning then individual tuition can be given. This has an advantage over the other two styles that if the first groups of users are enthusiastic they can be used to 'sell' the benefits of the LIMS to other potential users by word of mouth. Care in the selection of the first group, therefore, is essential.

### **Project Close-Out**

Once the system is operational, the project team should formally close the project and hand the system over to the system manager. Normally the project team will disband; however, in the authors view, it should undergo a metamorphosis to become a 'departmental LIMS user group', which would be responsible for the future development of the system, monitoring its use, highlighting and solving problems, etc.

### **Postimplementation Review**

Usually after 6 months of operation the system should be reviewed. This should be a formal process where the actual performance of the LIMS in relation to the claims made at the project proposal or the purchase justification will be critically evaluated. Successes, failures, advantages, and problems should be documented: it is only now that the consequences of the decisions and actions that the project team took during the SDLC will be seen. It is essential for the organization that the successes and the failures be recorded and applied to other computing projects that either are ongoing or that will be initiated in the future.

### **Enhancement of the System and Controlling Change**

Once the initial configuration of the LIMS has been established, it will inevitably undergo change. This change comprises two areas.

The first area concerns the repair of hardware where a part is replaced due to malfunction, which should be logged in an instrument book to show the repair and maintenance records similar to an analytical instrument.

The second area of change involves the software: when an error is detected and remedied (by changing the code of the program) the software changes from one unique state to another. What is unknown is how many errors have been created by fixing the original fault. Hence, there is the need to revalidate either the software module or the whole system when a fault is remedied. Therefore, any changes to the system should also be authorized, logged, and validated to demonstrate that the system is under control.

If a LIMS is successful then the users will request change, which should be encouraged as it is a natural outgrowth of the system and a normal part of the SDLC. The changes requested by the users should be discussed at a meeting of the users, where they will be authorized, modified, or rejected as appropriate. The enhancement, if approved, can be communicated to a vendor to implement as part of a general improvement to the standard package or they can be contracted to undertake the work as a separate task or it can be carried out in-house with the appropriate staff.

### Introduction

Clinical work is concerned with the understanding of disease, its diagnosis, and treatment. Those involved with clinical research or those concerned with patient care have a range of disciplines that may be applied to a problem under investigation. Most of these activities require the exercise of skill and expertise whether, for example, it is for surgery in heart disease, radiotherapy to treat cancer, or molecular biology to reveal the genetic basis for disease. Disciplines such as clinical biochemistry, hematology, immunology, will, therefore, focus on disease, diagnosis, and treatment but their application is largely (although not exclusively) associated with analytical procedures. They involve both quantitative and qualitative analysis of specimens of body tissues and fluids – and the interpretation of these results in the light of observations of the patient. The quality of analytical data is crucial to clinical science.

### Clinical Analysis

Requirement for quality in laboratory medicine is best illustrated by one or two examples.

1. For healthy subjects, the concentrations of calcium in specimens of plasma will be within the narrow range of  $2.2\text{--}2.6\text{ mmol l}^{-1}$  ( $88\text{--}104\text{ mg l}^{-1}$ ). For any single individual the concentration will be maintained within an even narrower range, varying by less than  $0.04\text{ mmol l}^{-1}$ . A concentration

increase of no more than  $0.1\text{ mmol l}^{-1}$  ( $4\text{ mg l}^{-1}$ ) or  $\sim 4\%$  is sufficient to indicate the presence of pathology of the parathyroid gland with the possible consequence of surgery being necessary for that individual. Thus, calcium in plasma has to be measured accurately and precisely within these ranges and without interferences.

2. Children with the inherited disease phenylketonuria are unable to metabolize a component of their diet (phenylalanine) and will develop irreversible brain damage unless they are provided with appropriate foods. This condition can be diagnosed soon after birth by examination of a small blood sample to detect the presence of phenylalanine. Tragic consequences ensue should there be an error in the test procedure and the diagnosis is missed. Regular inclusion of positive and negative controls is essential to demonstrate the reliability of the procedure.

### Quality Management Systems

Clinical chemists were among the first to adopt the concept of analytical quality assurance in the late 1940s. Early studies were simply *ad hoc* distributions of specimens and comparisons of results among a few established laboratories, but they clearly demonstrated large differences in the values obtained. This work revealed for the first time the need for quality assurance, not just in clinical laboratories but also within all areas of analytical chemistry and various quality practices evolved over several years. To provide a common basis for nomenclature and application of quality assurance within hospital laboratories, the International Federation of Clinical Chemistry compiled a series of recommendations in

This condition can be diagnosed soon after birth by examination of a small blood sample to detect the presence of phenylalanine. Tragic consequences ensue should there be an error in the test procedure and the diagnosis is missed. Regular inclusion of positive and negative controls is essential to demonstrate the reliability of the procedure.

### Quality Management Systems

Clinical chemists were among the first to adopt the concept of analytical quality assurance in the late 1940s. Early studies were simply *ad hoc* distributions of specimens and comparisons of results among a few established laboratories, but they clearly demonstrated large differences in the values obtained. This work revealed for the first time the need for quality assurance, not just in clinical laboratories but also within all areas of analytical chemistry and various quality practices evolved over several years. To provide a common basis for nomenclature and application of quality assurance within hospital laboratories, the International Federation of Clinical Chemistry compiled a series of recommendations in

the 1970s while practical procedures were described in several textbooks of clinical chemistry. Meanwhile, important features of management, particularly in the context of preclinical trial work were codified as Good Laboratory Practice. These different themes were eventually picked up in a systematic way in international standards. Thus, ISO 9001:2000 addresses generic issues of 'quality management systems', while ISO/IEC 17025:1999 focuses on the 'General requirements for calibration and testing laboratories'. The requirements of ISO/IEC 17025 were amplified and applied to clinical analysis in a document, 'Essential Criteria for Quality Systems of Medical Laboratories', prepared by the European Communities Confederation of Clinical Chemistry (EC4, [www.uni-oldenburg.de/ec4/](http://www.uni-oldenburg.de/ec4/)). A very similar document was published in 2003 as ISO 15189:2003 'Medical laboratories – particular requirements for quality and competence'. The valuable experience over more than 60 years of quality assurance in clinical analysis is effectively captured in this last standard.

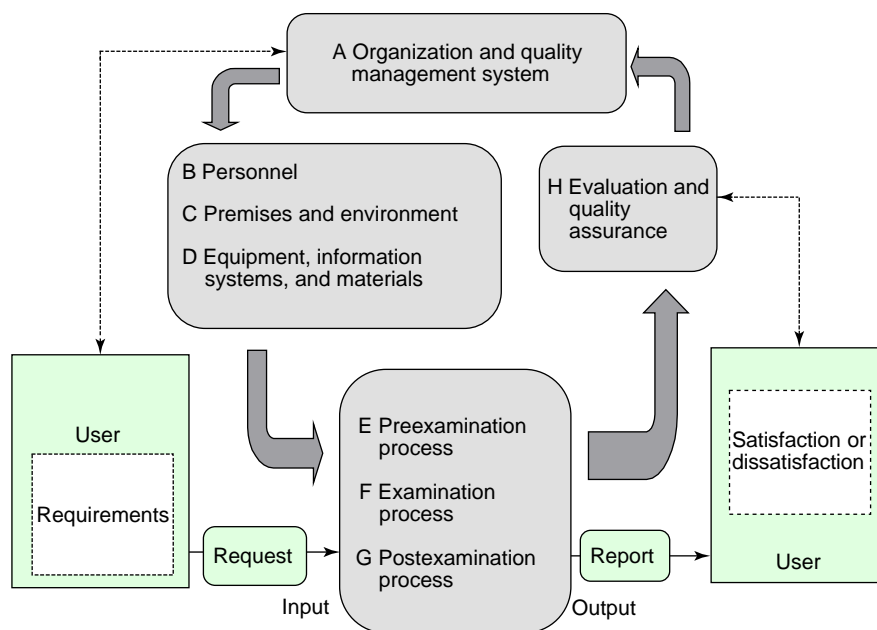

Alongside these developments has been the issue of accreditation, i.e., 'a procedure by which an authoritative body gives formal recognition that a body or person is competent to carry out specific tasks'. Those organizations responsible for accreditation of clinical laboratories draw extensively on the documents referred to above. ISO 9001 refers to a 'process based management system' in which elements of the quality management system (and,

therefore, of the work or process being undertaken) are subject to review and improvement to meet the requirements and comments of the user/customer. This may be viewed as a cyclical process where the work of the laboratory is periodically assessed in the light of user statements to modify the way in which the laboratory is organized and managed. One accreditation organization visualizes the process of laboratory organization and quality assurance in this way with its own accreditation standards (which are dependent on the ISO standards) forming essential components of the cycle (Figure 1). These concepts, together with extensive practical advice, are found in the guidebook by Burnett.

## Practical Approaches to Quality Assurance

### Introduction and Terminology

Analysts from different disciplines have adopted slightly different terms and also practical approaches to quality assurance. Recognizing this problem the international organizations for standardization have issued standards and guidelines addressing the definition of terms related to metrology, statistics, and analytical performances (International Vocabulary of Metrology, 1993; ISO Guide 30; ISO 3435, parts 1 and 2; ISO 5725, parts 1–6). In addition, a completely new concept has been introduced in 1993, with the ISO Guide on uncertainty of

**Figure 1** Relationship between a process-based quality management system and the CPA accreditation standards (from 'An approach to documentation in the medical laboratory'; [www.cpa-uk.co.uk](http://www.cpa-uk.co.uk)).

measurement, and, accordingly, the definition of terms related to analytical performances (namely within-run precision, between-run precision, and accuracy) have been revised to take into account this new development. Thus, the term 'accuracy' has been chosen to indicate the closeness of the agreement of an individual result with the 'true' value of the measurand. It is acknowledged that accuracy cannot be measured, but that the 'uncertainty' of measurement associated with a result, i.e., the interval of values that can be reasonably attributed to that measurand, may be determined. A new term, 'trueness', defines the closeness of the agreement of the mean of several results with an assigned value, and can be estimated as 'bias'. 'Precision' is a general term describing the closeness of the agreement between replicate measurements of the same sample by the same method. However, several different factors may affect estimates of precision and the terms 'repeatability' and 'reproducibility' are used to indicate two extreme conditions. Repeatability refers to measurements made under identical conditions, as far as possible (equivalent to within-run precision). Reproducibility is applied to estimates of precision that take account of all possible variables, including laboratories (more or less equivalent to between-laboratory precision). The term 'intermediate precision' refers to conditions lying between these extremes and it is recommended that the variables (time, operators, equipment, reagents, etc.) be indicated. As these terms are used in ISO 17025 and 15189 it is important to become acquainted with them. The complete definitions of the terms are given elsewhere in this Encyclopedia.

Although it is not universally adopted, most clinical laboratories now refer to 'quality assurance' with internal quality control (IQC) (intended to monitor precision and to detect significant changes in bias) and external quality assessment (EQC) (which can have a number of objectives including retrospective, independent supplementary checks on the effectiveness of the IQC procedures) as its major components.

### **Technical Components of Quality Assurance**

**Validation of a method** Method validation is the confirmation, by examination of objective evidence, that analytical procedures are appropriate for their intended use. Such evidence is generally already available for methods published as standards, or by recognized technical organizations. In other cases, such information may be included in the original published work or provided by the manufacturer of the equipment. Where an entirely novel method has

been developed, e.g., a procedure for the measurement by liquid chromatography of a new antibiotic agent in specimens of blood, or a mature method, e.g., the measurement of alkaline phosphates activity in serum with *p*-nitrophenylphosphate as substrate, is transferred to a different analyzer, performance characteristics need to be determined. Modifications to established methods may require only a limited study or a complete new validation, depending on the extent and importance of the changes.

The features to be determined to validate a procedure are repeatability (within-run) and intermediate (between-run) precision, limit of detection, limit of quantification, linearity of the response of the assay, specificity of the assay and whether there are any interferences, its trueness, the uncertainty associated with an individual result with a stated limit of confidence, and appropriate reference ranges. While examining these topics further information relevant to reagent stability, necessary frequency of recalibration, suitable IQC protocol, and overall assay weakness will be obtained.

**Precision** To measure repeatability one sample is repeatedly analyzed within a single assay batch. From the results given by this exercise the analyst can calculate the mean concentration, the standard deviation (SD), and the coefficient of variation (CV, sometimes referred to as the relative standard deviation, RSD). While there are no fixed number of replicates necessary for this measurement, it is usual to try and obtain at least 20 results, in order to ensure reliable statistics, and the number should always be stated in any description of the method's performance. The experiment should be repeated with further specimens having different concentrations of the analyte so that a clear indication is achieved of the precision over the range of concentrations that is measurable by the procedure (i.e., the precision profile). A similar series of measurements can be made to determine intermediate precision. Factors such as the preparation of reagents and calibration solutions, resetting of instrumental parameters, and the expertise of the analyst will contribute to the analytical variation. The influence of some of these variables can be critical and, unless great care is taken, the intermediate precision will be very poor. Inevitably, the CVs will be greater than the equivalent repeatability data.

Information derived from these experiments has two purposes. First, it can be decided if the methodological procedure is suitable for introduction into the repertoire of a laboratory. If the analytical variation is in excess of the resolution

needed for clinical applications it will not be possible to detect significant changes in patient condition with any certainty or confidence. The method will have to be improved or discarded. This issue of clinical need is separate from quality assurance but can only be understood in the context of good analytical performance. Attempts to quantify the requirements of analytical methods for clinical purposes (quality specifications) have been developed for individual analytes, on the basis of normal intraindividual day-to-day (or hour-to-hour) variations, or as a function of their reference ranges. While these calculations can be helpful, in practice, the fundamental goal is to achieve as good precision as is practicable. Second, the data provide the guidelines for IQC protocols (described later).

*Limit of detection (LOD) and limit of quantitation (LOQ)* If the analyte concentration is always at a level that is so high that sensitivity is not a problem, e.g., hemoglobin in blood, calculation of the LOD is unimportant. For a large number of other parameters the concentrations will always be very low. The LOD must be established so that a result can be quoted with an assurance that it has validity and does not represent an extreme of the background 'analytical noise'. With many investigations it is necessary to confirm whether or not a substance (e.g., HIV antibody) is present in the specimen. In these cases the minimum amount that can be determined must be known so that the sensitivity of the analysis can be considered when deciding if further action is necessary. The LOD is influenced by the inherent sensitivity of the instrumentation and by the methodological imprecision. To measure the LOD a specimen giving a reading close to that of the reagent blank should be analyzed with a large number (10–20) of replicates. The concentration equivalent to that of the reagent blank plus three times the SD of the series of results thus obtained represents the LOD. Although the LOD provides information on what can be distinguished from the blank, a high level of imprecision will affect the measurements of concentrations close to the blank. It is therefore sometimes useful to calculate the LOQ, i.e., the lowest concentration of an analyte that can be determined with acceptable precision (repeatability) and accuracy under the stated conditions of the test. If the accepted level of repeatability is taken as 10%, the LOQ can be calculated from the same series of data as the concentration of the reagent blank plus 10-fold the observed SD.

*Linearity of calibration graph* A simple experiment involving analysis of a series of standard solutions

can provide valuable practical information and show how many calibration standards are needed for an assay, i.e., whether or not the calibration graph is a straight line, and at what point does the graph flatten out and it becomes necessary to dilute specimens with high concentration of analyte. Regression analysis is not sufficient to establish linearity and visual inspection or the analysis of residues will give more information.

*Interferences* Most specimens of clinical importance have complicated and variable matrices. As a consequence there are many factors that can influence accuracy and have to be considered in the characterization of new or modified methods. Procedures to establish that a method is providing unbiased results will be considered in a later section but the features of biological systems and clinical specimens that can cause erroneous results include:

- Direct methodological interferences. Serum collected from patients with renal failure has increased concentrations of compounds such as urea while high levels of bilirubin are found in specimens from subjects with liver dysfunction. These are known to interfere (positively and negatively) with many analytical methods. Lipemic specimens cause light scattering that may produce aberrant results in spectrometric assays.
- Metabolites may be more or less active than the parent biomolecule, but a nonspecific methodology that is unable to differentiate between the various forms gives misleading results.
- A biological, protein-based matrix is more viscous and contains a high concentration of dissolved inorganic salts. The complex matrix can reduce the speed of pipetting and lead to differences in handling characteristics by tubing, syringes, etc., when compared with aqueous calibration solutions, and give erroneous results.
- Pathological conditions can give rise to sudden and unexpected large changes in the concentrations of a metabolite to be measured. Dilution of the specimen to allow quantification will adjust other components of the sample and may result in subtle changes to the measurement.
- Very many of the specimens collected for clinical investigation are from patients receiving drug treatment. Interferences associated with pharmaceutical agents or their metabolites are well recognized and documented.
- Measured concentrations can be influenced by characteristics of the methodology. It is usually unwise to rely entirely on data determined elsewhere

to define the concentrations within normal populations or associated with particular clinical states. A series of investigations to confirm or establish reference ranges should be undertaken.

At the conclusion of these experiments the analyst should have a complete set of information to characterize the method, with relevant figures of merit, review of interferences, speed and costs of the procedure, and data to indicate more qualitative features such as robustness and the degree of technical skill required for regular use.

**Internal quality control** The inherent imprecision of a method will have been determined as part of the validation, as it was implemented within the laboratory (intermediate precision). The information can then be applied to the IQC program that is designed to identify the intrusion of a bias and/or an alteration in the precision of the assay. Factors that can contribute to a bias or change in precision include:

- instrument stability or drift,
- deterioration of reagents,
- errors associated with the calibration material,
- problems with equipment, e.g., partial blockage within a dilutor or a shift in the monochromator calibration on a spectrometer,
- human errors, e.g., use of incorrect reagents, instrument settings, etc.

An IQC program can comprise several elements, but the most usual is to include a specimen(s) with known (or target) concentration/result within each batch, and to take that specimen(s) from a large stable pool so that it can be used in this way over a period of several months or longer. The precision of the method will show the analyst the allowable range of results to anticipate around the target concentration. An acceptance range of  $\pm 2SD$  is usually applied but these limits should not be so wide as to deprive the analysis of useful clinical value, a point that should be evident at the time when the method is developed and introduced into the laboratory repertoire. The practical approach is to draw a Levey–Jennings chart with the results of the IQC specimen(s) plotted (Figure 2). A series of decision criteria or ‘control rules’ have been developed by Westgard ([www.westgard.com](http://www.westgard.com)) for use with this type of chart. Westgard rules guide the analyst as to the number and concentration of IQC specimens to be included, the frequency of inclusion within a test run, and how QC results can be applied to decisions as to whether a run should be accepted or rejected. Results

**Figure 2** Results for an IQC specimen shown on a Levey–Jennings chart. This example presents four analytical scenarios: (A) good control where points are evenly distributed above and below the target concentration and  $\sim 95\%$  are within  $\pm 2SD$ ; (B) a sudden shift in accuracy – perhaps the calibration material has become contaminated; (C) a gradual shift in accuracy – perhaps the substrate solution has exceeded the expiry date; (D) very poor precision – perhaps a valve is sticking and causing erratic transfer of sample. Other types of display are proposed from time to time, which are claimed to offer increased sensitivity to detect errors. The Levey–Jennings plot, however, is very widely used.

determined for patients’ samples should be reported only if the concentration of the IQC specimens satisfies preset criteria, whether the Westgard rules or those set internally by the laboratory.

In addition to the systematic inclusion of quality control specimens as part of the analytical process there are other procedures that can be incorporated into the IQC program. These tests are usually applied to methods that are undertaken on a regular, almost daily, basis. They involve the carry-forward of specimens and the calculation of batch/day means. The sensitivity of daily mean plots is increased by the CUSUM technique (<http://www.westgard.com/lesson14.htm>).

Some analytical equipment include routines for calibration and quality control of analyses that are predetermined by the software developed by the manufacturers. In these circumstances, the principles and practices elaborated above may be unrealistic and analysts are forced to follow protocols as directed by the equipment.

No clinical laboratory should operate without an IQC program, but whatever approach is adopted the program will fail to have any impact unless it is accompanied by a well-defined policy for further action. The policy will form part of the quality management system and will describe the ways in which results of IQC specimens are to be recorded, the members of staff who should scrutinize these data, and the possible decisions that they can make. The outcomes of a properly implemented IQC program should be the early detection of errors or

analytical problems, the maintenance of a known level of performance even if there are changes among staff, departmental routine, or even relocation of the laboratory, and prolonged experience of a procedure that can act as a 'benchmark' against which alternative methods can be compared.

**Accuracy and external quality assessment** ISO 15189:2003 requires both the use of validated methods and the estimate of the uncertainty of measurement (i.e., the inaccuracy) associated with the individual results. To fulfill this requirement, determination of the method bias (trueness) is always necessary. In practice, trueness can be examined from two approaches. First, there is the estimate that should be part of the initial validation of the method (or a review if problems are found to have developed). An extension of this involves work with definitive and reference methods, primary standards, and reference materials and the traceability of results to SI units. A statement of the uncertainty of measurement should accompany each comparison and contribute to the estimate of the total uncertainty of measurement of the result. To this aim, manufacturers of *in vitro* medical diagnostic devices are now compelled to give information on the traceability of the results obtained using their products and further developments are to be expected in this field. The second approach to determination of trueness in the medical laboratory involves EQA. This has several synonyms, e.g., interlaboratory comparisons, round-robin exercises, or proficiency testing programs. In part, this work represents an ongoing surveillance of accuracy to supplement the laboratory's IQC program but EQA can fulfill a number of other functions including the provision of materials for which the concentration of analytes is known with reasonably good accuracy. These reference materials can subsequently be used for initial characterization or review of methods, or for the evaluation of instrument performance.

**Measurement of trueness** Wherever possible, investigations of the trueness of a method should include analysis of reference materials (RMs). The value of RMs for IQC has already been discussed but for studies of trueness it is those RMs with previously determined and well-defined concentrations of analytes that are required. The essential features of RMs, stability, homogeneity, composition of matrix, etc., are reviewed elsewhere in this Encyclopedia, but it is important to indicate here how the concentrations of clinical RMs may be derived and the degree of confidence that can be attributed to the stated levels. Certified reference materials (CRMs) are those with

concentrations defined with the smallest uncertainty and thoroughly documented. For clinical applications, however, the determinands that are present in CRMs are few in number and do not include most of those that make up the repertoire of clinical laboratories. Reliance has to be placed, therefore, on the 'assayed quality control' specimens (see below). Manufacturers of these specimens have different practices to determine the 'assayed values'. These include in-house measurements, results obtained by a limited number of expert laboratories, and distribution via an EQA scheme to a large number of laboratories to give consensus data. Almost certainly the assigned concentrations will be given together with an indication of the methodologies so that methodological biases can be taken into consideration. In addition to commercially available assayed RMs, the organizers of EQA schemes usually have specimens that are surplus to the requirements of the scheme. Organizers are generally willing to respond favorably to requests for one or more aliquots of the specimens and the relevant consensus data from the scheme.

A second experiment to investigate trueness is to calculate the recovery of a known amount of analyte added to a suitable specimen. Quantitative recovery from normal biological fluids must be followed by further experiments to determine whether there are interferences associated with pathological specimens. However, recovery experiments are not always possible in the clinical laboratory because many of the items that have to be measured, e.g., enzymes and immunoglobulins, are not available in a purified form.

Further studies on trueness are particularly valuable for newer work when the analyte under investigation is not included in any RM or EQA program. A series of specimens can be exchanged between laboratories and if the results obtained by the partners are not in good agreement the analysts must conclude that there are problems with trueness. This approach does not necessarily reveal interferences or biases associated with the technique and, therefore, it is desirable to take in addition a series of specimens for measurement by the method under investigation and by a method that involves an entirely different analytical technique.

**External quality assessment** Many countries have authoritative, regular, structured provision for EQA for at least general clinical laboratory work (biochemistry, hematology, microbiology). There are also large numbers of specialist EQA schemes, often international, for those analytes measured in fewer laboratories. In addition, schemes to monitor

laboratory activities that do not have a quantitative outcome, e.g., histological examination of tissue, the interpretation of analytical data, etc. are available.

As they play such an important role in the assessment of laboratory performance, a number of documents have been produced, suggesting minimal requirements for the managerial and technical aspects of EQA schemes. The issues addressed in these documents have been mainly integrated in the guide issued by ISO (ISO 43:1997, Parts 1 and 2) and the CPA standards for the accreditation of EQA schemes ([www.cpa-uk.co.uk](http://www.cpa-uk.co.uk)). The ISO standard for the accreditation of medical laboratories (ISO 15189:2003) also indicates that the laboratory should participate in EQA schemes that are substantially compliant with the requirements of the ISO guide.

Organization of EQA schemes consists of up to four components:

- management,
- data reduction,
- preparation of reports,
- assessment of laboratory performance.

Management of the EQA scheme is concerned with procurement and/or preparation and distribution of good quality specimens with analytes at concentrations appropriate for the needs of the participants, and at a volume consistent with usual laboratory routines. The number and frequency of distribution will be determined together with the time allowed for the analysis and return of results.

Data reduction involves the mathematical procedures applied to the results returned by the participants. Usually, there is a procedure to identify 'outliers' – results that are remote from the anticipated value, probably caused by a transcription error or analysis of a different sample. As inclusion of these results could distort subsequent calculations it is useful to apply a statistical routine (e.g., greater than  $\pm 3SD$ s from the mean) to eliminate these data. The 'trimmed' data are then taken through the chosen calculations that, with few exceptions, are determination of the number and range of results, the mean, SD, and CV. If it is suspected or has been definitely shown that the distribution of data is not normal, the median should be found. In schemes where there are hundreds of participants, subroutines are included to re-examine results and present these calculations for a specific method or other variable.

The operation of so many EQA schemes, with their own computer programs for the preparation of reports, makes it inevitable that reports will be very

different in appearance. Most organizers are so familiar with what they are doing that they are certain that participants will immediately comprehend the significance of all the calculations and information that is laid before them. This is a rash assumption and a clear display, logically laid out on a page with the salient features prominently positioned, is required. Bespoke reports that identify the result from the individual laboratory and its relationship to other participants are preferred. Where schemes include a large number of analytes it is helpful to provide a one-page summary of the participants' performance at the front of the report.

While a laboratory can review its own results against those of the other participants and decide if analytical performance is satisfactory, it has been shown that improvements are most effectively stimulated by a more formal independent assessment that includes some kind of measure or score. Scores allow laboratories to be compared and participants can look at their own performance relative to that of other colleagues. Changes in performance over time, within a single laboratory, are also revealed by regular calculation of a score.

As with report formats, performance assessments may be idiosyncratic to a scheme but some consistency in approach has been recommended in ISO 43:1997, which recommends use of the  $z$ -score, which is

$$z = \frac{x - X}{s}$$

where  $x$  is the laboratory result,  $X$  the target concentration, and  $s$  an appropriate estimate/measure of variability that is selected to meet the requirements of the scheme organizer. The  $s$ -value can be determined from data derived from the results of the participants of a particular scheme or in other ways, e.g., the SD achieved by reference laboratories. Scoring systems have undoubtedly prompted enormous improvements in performance and in established schemes that have run for several years; results reported by most participants are in close agreement and indicate good accuracy.

A further step in the application of EQA to laboratory performance is to establish quality specifications, i.e., performance scores that are indicative of good and poor performances and to a degree of quality to which all participants should aspire. Performance assessments are prepared for the benefit of participating laboratories and their users. In addition, performance scoring can be employed to assess the competence of laboratories where licensing is required.

The International Federation of Clinical Chemistry Working Group on Quality Control defined the functions of EQA schemes as:

- To supplement a laboratory's IQC procedures.
- To measure the performance of individual laboratories for comparison with other participants, or for changes with time (to which licensing and/or accreditation could be added).
- To obtain consensus concentrations for specimens.
- To investigate features within a laboratory that contribute to performance; e.g., method, size of laboratory, work load, test frequency, equipment, etc.
- To measure the 'state-of-the-art' for a test.
- To act as an educational stimulus.

The first three features in the list have been covered in the previous pages; the remaining aspects, especially that concerned with identification of reliable methods, etc., are relevant to laboratory management (see below).

It was emphasized at the beginning of this article that analytical accuracy is crucial to diagnosis and treatment of many clinical conditions. As with IQC, the laboratory must have a clearly defined policy to describe action taken on receipt of a report from an EQA scheme. Those involved with organization of such schemes can provide many examples of horror stories where reports have been ignored or deliberately suppressed on receipt, rather than admit that a problem exists. This type of bad and potentially

dangerous practice cannot occur if senior managers enforce the policy.

### Managerial Components of Quality Assurance

Laboratory management is typically concerned with general organization and policy arrangements, all of which contribute to quality. This will include selection and training of staff, evaluation, purchase and maintenance of equipment, selection of analytical methods, document control, protocols for clinical investigation, and audit. Other management topics such as preparation and issuing reports, corrective actions, resolution of complaints, risk assessments, and health and safety are equally relevant to quality assurance and all should form part of the departmental quality management system but are outside the scope of this review.

This article is reproduced from the first edition, pp. 4261–4280, © 1995, Elsevier Ltd., with revisions made by the Editor.

A fundamental consideration in the reliability of any analytical measurement is that of sample quality. Sample quality may be appraised on the basis of the quality of the resulting chemical, physical, and biological measurement data.

Assurance of acceptable data quality requires a system which ensures that all activities associated with the sampling program be well defined and supported by accepted and standardized practices.

### The Need for a Water Quality Field Sampling Quality Assurance/Quality Control Program

A field quality assurance/quality control (QA/QC) program must ensure the integrity and representativeness of the samples taken from aquatic sources such as surface waters, groundwater, and marine environments.

If nonrepresentative samples are collected, and sampling preservation techniques are inadequate, the quantitative results will be invalid. Emphasis must not be placed only on the collection of samples that are appropriately representative of the aquatic source from which they are taken, but also on the

appropriate preservation, transportation, and handling procedures that are used in the life of each sample in its journey between the collection site and the laboratory. In addition to the need for representativeness of samples, the data produced from the samples must be of known quality, sufficient to meet the needs of the sampling network and its data users. Some desired characteristics of data quality are accuracy, precision, confidence limits, data completeness, data compatibility, and data comparability.

### **QA/QC Documentation**

For a field sampling quality assurance/quality control (QA/QC) program, there are three documents that are required. The first is the 'Quality Assurance Program Plan', which commits management to a QA policy and sets out the requirements for data needed to support program objectives. The program plan describes the overall policies, organization, objectives, and functional responsibilities for achieving data quality goals.

The second document is the 'QA Project Plan', a technical document that specifies the QA and QC requirements for each project. The plan specifies any QA/QC activities required to achieve the data quality goals of the project. It describes how all data are assessed for precision, accuracy, completeness, comparability, and compatibility (components of data quality criteria and objectives). The QA Project Plan further requires that all data generated be thoroughly documented, and be in sufficient detail to permit unambiguous evaluation of project results.

The field sampling QA/QC manual is also a component of the QA Project Plan and must provide guidance on policy and procedures. This manual will contribute to the quality of the data generated.

The third document that is needed is a 'Program Implementation Plan'. A number of mechanisms must be put in place to ensure maximum coordination and integration of QA efforts within the overall program (covering sampling, laboratory analysis, and data handling). Management committees directing water quality programs must coordinate the monitoring and survey programs to ensure that data of known and acceptable quality are produced. Resource levels, schedules, turn-around times, responsibility centers, performance indicators, milestones, risk factors, implications, emerging issues, etc., must all be given attention, if the programs are to succeed.

## **Designing a Water Quality Monitoring Plan**

### **Sampling Programme**

The field QA/QC strategy includes a sampling plan which serves as the central element for directing the various operational activities. To produce a truly effective sampling plan, an interdisciplinary approach is necessary. The interdisciplinary contributions assure the development of a plan that is specific and has all the requirements for successful sampling operations.

The sampling plan must concern itself with the 'why', 'what', 'where', 'when', and 'how' questions. The 'why' question must address the broad objective(s) of the monitoring program, and the data quality objectives associated with the various specified projects. The rationale for each project should include an estimation of the project's utility and cost-effectiveness. The 'why' question can be influenced by considerations such as prevailing environmental concerns and problems; a combination of socioeconomic, sociopolitical, and environmental issues; the need for continuing and/or expanding existing projects or programs, and the need to provide baseline data at new specific sites.

The 'what to sample' should be a logical sequel from the answer to the 'why to sample' question. Specific water quality parameters may be issue-oriented, or may result from water quality objectives arising from negotiated water quality agreements between concerned and/or interjurisdictional water industry agencies.

The choice on 'where to sample' may be controlled by the decisions taken on the 'why to sample' and 'what to sample for'. However, once a macro-level choice (river basin, lake, or stream) has been agreed upon, selecting sampling stations (micro-level choices) is an exercise controlled by a number of exogenous and endogenous factors. These factors include hydrological data (flow rates, sediment discharges, etc.) for various sections of the aquatic body; topography of the macro-site; geographical location with regard to interjurisdictional boundaries; ease of access to sampling sites; runoffs and material infusions (sediment, water, sludge, sewage, etc.) from external sources; mixing currents; water depth; and anthropogenic activity.

The 'when to sample' choice is influenced by, for example, (1) objectives of the study; (2) available resources; (3) seasonality, including spring runoff, heavy snowfall, and heavy rainfall; (4) required estimated sampling frequency; (5) high or low flow rates within the sampling cross-section of the

aquatic body; (6) unusual environmental and ecological occurrences such as flooding and chemical spills; (7) intentional or unintentional toxic waste discharges; (8) anthropogenic activities which may be deleterious to the aquatic body; and (9) the density of airborne and nonpoint source pollutants.

The appropriateness of 'how to sample' can be addressed by consideration of nine principles:

1. Preliminary sampling, such as a pilot survey, should be conducted in order to provide basis for an evaluation of the sampling design and the statistical options.
2. Replicate samples should be taken with each combination of time, location, and any other controlled variable. Differences 'among' can only be demonstrated by comparison to differences 'within'.
3. An equal number of randomly allocated replicate samples should be collected for each combination of controlled variables. Collecting samples from 'representative' or 'typical' places is not random sampling.
4. Verification should be made that the sampling method is correct for the range of sampling conditions to be encountered. Note that variation in efficiency of sampling can bias 'among-area' comparisons.
5. If the area sampled has a large-scale environmental pattern, it should be broken up into relatively homogeneous subareas, and sample collections should be proportioned to the size of each subarea.
6. The sample size should be verified as appropriate to the quantity and spatial distribution of the parameter. An estimate should then be made of the number of replicate samples required to obtain the necessary precision.
7. To test whether a condition has an effect, samples should be collected both where the condition is present and absent, but all else is the same. An effect can only be demonstrated by comparison with a control.
8. On-going site evaluations for parameters such as pH, conductivity, turbidity, and dissolved oxygen should be incorporated into the sampling plan, with some consideration given to the possible need for more extensive studies at sites where specific problems have been identified.
9. The data from the pilot survey(s) should be tested and analyzed to determine whether the error variation is homogeneous, normally distributed, and independent of the mean. If this is not the case (a situation which is highly probable with biological parameters), then the data could be appropriately transformed, or distribution-free (nonparametric) procedures could be used.

## Site Selection

Site selection must be given detailed consideration during the development of the 'Sampling Programme Plan', since sampling techniques to be used in a given situation will depend not only on the data needs, but also on the nature of the flow and other conditions.

Appropriate siting is critical to the success of the monitoring network. Poor siting could result in low-quality, unrepresentative data. It is therefore important that comprehensive quality assurance/quality control procedures (QA/QCPs) be developed to address network siting. These procedures should be designed to meet a specific set of quality assurance objectives, namely:

- to assure that the geographical distribution of sampling locations meets network objectives;
- to ensure that the sampling sites (micro-locations) that are chosen are appropriately representative of the existing aquatic characteristics of the given water body; and
- to ensure that site documentation is sufficient for data users to assess the suitability of the sites for the required purposes.

Meeting these QA/QC objectives requires the implementation of the following procedures:

- Conducting a preliminary site assessment, followed by a report prepared within the first six months of operations, so that obvious problems are detected early, and the site can be changed before a large data set is obtained.
- Routine reporting of significant changes in data obtained from the site during period-to-period sampling.
- Proper documentation of sampling sites during program operations.
- Independent quality assurance audits of sampling sites. This should be conducted in order to (1) assess independently the accuracy and completeness of current site documentation, and (2) to assess the representativeness of each site with respect to its monitoring objectives. Site representativeness could be checked by looking at data for a number of physical parameters (turbidity, pH, conductivity, and dissolved oxygen).

Apart from using objectives to allocate sampling stations, other factors such as size of aquatic source and available resources must enter the selection scheme so that a reasonable degree of optimization can be achieved. Resources may be allocated on the

basis of the size of the aquatic source, sampling frequency, number of sampling sites within a macro-location, site accessibility, and distance of site(s) from the office which is coordinating or conducting the sampling operations. Different aquatic sources (rivers, lakes, streams, estuaries, etc.) require different or varying approaches in the selection of sampling stations.

**General considerations for station location** As a general rule, past or present monitored sites should be taken into account when locating a water quality sampling station, to ensure a long-term continuity in data sets or to identify seasonal cycles. Water quality monitoring stations should be located close to water quantity stations when these exist already, in order to facilitate the study of water quality–quantity relationships. The distance between the collection site and a gauge recorder should not be more than 60 to 80 m, unless it has been ascertained that there is no appreciable inflow between sites. If there is no gauging station at or near the sampling site, a discharge measurement should be made at the time of sampling.

### Sampling Frequency and Sample Size

Many water quality monitoring jurisdictions perform monthly sampling, but the day of the month and the time of the day may vary randomly. In the majority of cases, sampling is related to the estimated variance in the measurements of the water quality constituents of concern.

The simplest design case on a single station-single variable basis would be to select the sampling frequency which results in the desired confidence interval width about the annual mean (or geometric mean) for the specified water quality variable at the specified site. If the estimate of the variance (obtained from historical data or a pilot program) is assumed to be the population variance ( $\sigma^2$ ), then the number of samples  $N$  (per period) required to obtain a given degree of confidence in estimating a mean value for the parameter of interest, can be derived from the following equation:

$$N \geq Z_{\alpha/2}^2 \cdot \sigma^2 / E^2 \quad [1]$$

where  $Z_{\alpha/2}$  is the standard normal deviate corresponding to a probability of  $\alpha/2$ , and  $E$  is the error term, and is given by  $\mu - x$  for any specific or chosen value ( $x$ ).

If  $s$  is used instead of  $\sigma$ , and  $t_{\alpha/2}$  (Student's  $t$ ) is used in place of  $Z_{\alpha/2}$ ,  $N$  is given as

$$N \geq t_{\alpha/2}^2 \cdot s^2 / E^2 \quad [2]$$

A number of sources have provided a very comprehensive outline of methods for determining sampling frequencies for 'single station-single variable'; 'single station-multiple variables'; and 'multiple stations-multiple water quality variables'. The following is an example of the use of eqn [1].

'The samples to be measured for a given parameter are expected to have a mean annual concentration of  $\sim 0.1 \mu\text{g ml}^{-1}$  with a standard deviation of  $0.05 \mu\text{g ml}^{-1}$ , and the tolerable error in the stated value of the mean at the 95% confidence level ( $Z = 1.96$ ) is not to exceed 20% ( $0.02 \mu\text{g ml}^{-1}$ ). If it can be assumed that the measurement error is small in comparison with the measured values, find the number of samples required per year to estimate future annual means for the given parameter.'

With the above values, the number of samples required will be

$$N = (1.96)^2 \cdot (0.05)^2 / (0.02)^2 \\ = 24 \text{ samples per year, or two samples per month}$$

The appropriate size of samples to be collected for any given parameter will depend on the estimated natural concentration level of that parameter within the aquatic source. The smaller the existing analyte concentration, the larger the volume necessary for obtaining a reasonable measurement (a measurement equal to or greater than the limit of quantification after volume reduction).

For organic analytes, samples of 100 liters or more are collected for solvent extraction. New field *in situ* solvent extraction techniques are now providing alternatives to handling large liquid volumes. However, for a number of diverse parameters, there is still a need for estimating the sample volumes required to measure levels of interest. A number of empirical and semi-empirical methods have been developed for determining sample sizes so as not to exceed a predetermined level of sample uncertainty. One approach is based on the knowledge that the between-sample standard deviation decreases as the sample size increases.

A modified form of the Ingamells' equation can be adopted to determine the sample volume that is required for an estimated standard deviation and a predicted sampling uncertainty. The equation is of the form:

$$VR^2 = M_s \quad [3]$$

where  $V$  is the volume of sample analyzed,  $R$  is the relative standard deviation (in %) for repeat measurements on the sample analyte, and  $M_s$  is the sampling constant, corresponding to the volume of

sample required to limit the sampling uncertainty to a chosen percentage value (e.g., 1%) with a proposed level of confidence (e.g., 68%). The magnitude of  $M_s$  can be determined by estimating the between-sample standard deviation  $S_s$  from a series of measurements of samples of volume  $V$ . Once  $M_s$  is evaluated for a given sample, the minimum volume  $V$  required for a maximum relative standard deviation of  $R\%$  can be calculated.

An example of the use of  $M_s$  is as follows.

'Estimate the volume of sample to be collected for the analytical measurement of a given parameter, when the values of  $M_s$  and  $R$  are given as 100 ml and 20%, respectively'.

Inserting the values of  $M_s$  and  $R$  into eqn [3],  $V$  is calculated as

$$V = 100 \text{ ml}/(0.2)^2 = 2.5 \text{ l}$$

When a decrease of the original volume (via solvent extraction, distillation, or evaporation, etc.) is required before analysis, back calculations must be carried out to determine the original volume that must be collected to give the desired measurable level of the parameter. For example, if  $V_1$  is the volume calculated from the use of  $M_s$  and  $R$ , then the required original volume  $V_0$  is obtained from the product of  $V_1$  and the volume reduction factor. For a volume reduction of 100,  $V_0$  would be  $100V_1$ .

Another form of the Ingamells' equation:

$$WR^2 = K_s \quad [4]$$

can be applied to measurements involving bottom sediment samples.  $W$  represents the weight of the sample analysed,  $R$  has the same meaning as in eqn [3], while  $K_s$  replaces  $M_s$  in the same equation.

Whether volumes or weights are being considered, every effort should be made to assure homogeneity in the sample matrix before any subsampling is carried out.

### Field and Laboratory Analytical Practices

The sampling plan must consider the role of good field and laboratory practices. The basic QA/QC field testing and laboratory analytical protocols that will be adopted must be spelt out in the sampling plan. For the laboratory, the scope of both the intra- and interlaboratory QA/QC programs should be referenced, and should be consistent with the size of available resources.

The performance of an instrument must be checked and appraised by a qualified person before being transported to the field. This involves a visual inspection and verification of its operation including the zero and full-scale calibration. Documents on

standardization, calibration, maintenance, equipment safety, and spare parts should accompany each instrument.

The standardization of instruments should be performed using reference standards when these are available, or against certified standard instruments. This must be done before the instrument is transported to the field, or in some cases the reference instrument could be transported to the field and employed under actual field conditions. Laboratory standardized instruments should be rechecked upon arrival in the field.

Calibrations must be conducted under the same instrumental and chemical conditions as those that will exist during the measurement process. The frequency of calibration will depend on the accuracy requirements of the investigation and on the stability of the instruments. Daily calibration checks are recommended when the instrument is in daily use, or at other times, immediately prior to a series of measurements. For unstable instruments, the calibration should be checked before each series of measurements, between measurements, and after the last measurement.

The calibration process is vital to all measurements and should be governed by a calibration plan. Such a plan should provide for:

1. calibration procedures and record forms;
2. stated calibration frequencies;
3. appropriate sources for obtaining certified and high quality standards, or the best means of producing accurate in-house standards;
4. a list of all calibration standards (including nomenclature and assigned identification numbers);
5. specifications of environmental conditions; and
6. intended range of validity.

The sensitivity of each analytical method is an important characteristic, and must be known. The precision and accuracy of measurements must reflect the level of confidence placed on the measurements.

The accuracy required from the measuring system should be determined by the objectives of the sampling program, and by the use of the data. The measurement system should avoid superfluous and expensive accuracy and precision determinations if there is a failure in the monitoring program to meet the stipulated objectives. The analytical measurements must also be rugged and complete.

### Cost Considerations

Program managers involved with water quality monitoring program must be concerned with program cost-effectiveness. The operation of a quality cost

system would help to lessen the cost of operational activities which are directed toward controlling data quality. The basic concept of the quality cost system is to minimize total quality costs through proper allocation of planned expenditures for the quality assurance and quality control efforts, while maintaining an acceptable level of data quality.

The quality cost system structure provides a means of identification of quality-related activities and for organization of these activities into prevention, appraisal, and failure cost categories. These categories are defined as follows:

- Prevention costs are associated with planned activities whose purpose is to ensure the collection of data of acceptable quality and to prevent the generation of data of unacceptable quality.
- Appraisal costs are associated with measurement and evaluation of data quality. This includes the measurement and evaluation of materials, equipment, and processes used to obtain quality data.
- Failure costs are incurred directly by the monitoring agency or organization producing the failure (unacceptable data).

There is no preset formula for determining the optimum mode of operation. Rather, the cost-effectiveness of quality costs is optimized through an iterative process requiring a continuous analysis and evaluation effort. Maximum benefits are realized when the system is applied to a specific measurement method in a stable long-term monitoring program. For example, a monitoring program with a fixed number of monitoring sites, scheduled to operate for more than a year, would be a desirable candidate for a quality cost system.

The size and diversity of a water quality monitoring operation is an important determining factor in decisions related to formalization of the QA program. Operations concerned with defined programs of work may be more easily adaptable to formal QA activities, and the program costs can be more easily justified. For operations involving numerous repetitive measurements, a formal quality assurance program is a necessity, and the time and effort devoted to its development should be compensated by cost-effective reliable analytical data. The overall cost of the QA/QC activities should not exceed 15–25% of the total monitoring operational effort, and ‘repeats’ and lost data should be minimized.

### **Training of Field Personnel**

All personnel involved in sample collection, field analysis, data reduction, and QCPs must be adequately trained. They must be made aware of the

importance of obtaining data of known quality, must become familiar with the quality assurance program, and must be knowledgeable about the various ways of achieving and maintaining good quality data.

Training personnel for field operations will involve a broad range of disciplines, because of the diversified requirements (mechanical, physical, chemical, biological, hydrological, etc.). Personnel training must start before operations begin, and must continue during operations, with periodic reviews and retraining when indicated or required.

To maintain and foster consistency in the quality of collected data, all field personnel (particularly new employees) should become familiar with project objectives, sampling protocols, station location, equipment operation, and safety rules prior to the commencement of field work.

Suggestions for general on-the-job training for sampling and field-testing personnel, include:

1. studying operation manuals and the sampling program plan;
2. observing a trained and experienced operator perform the various tasks in the data collection process;
3. performing field operations under the direct supervision of a trained and experienced person, and then independently performing operations related to instruments, sample collection, sample analysis, and data handling;
4. attending and participating in in-house seminars which are directed towards problem solving and confidence building;
5. gaining experience and acquiring new skills and technical information through interchange programs between various water quality agencies, in cases where the interchange becomes a beneficial exercise; and
6. announced and unannounced periodic proficiency testing of operational personnel to determine the need for additional training.

### **Field Trip Preparation**

Before starting out on a water quality data collection trip, field personnel should determine the types of samples that are to be collected and the field measurements required to assemble the proper sampling and testing equipment. Field personnel should also ensure that the equipment being transported to the field is in good working order and that there are spares available for those pieces of equipment which are hard to replace once out in the field. Environment Canada’s manual on *Sampling for Water Quality*

(1983) gives a detailed outline of necessary preparation for field trips. The preparation entails:

1. obtaining specific instruments on sampling procedures;
2. preparation of an itinerary according to the sampling schedule;
3. preparation of lists of required equipment, supplies, and materials;
4. ensuring that all sample containers, covers, and attachments have been cleaned in accordance with standard procedures, and that they are safely packed;
5. ensuring that the laboratory has prepared the chemical reagents and standards needed for the trip; and
6. preparation of checklist (including road maps, station location descriptions, field sampling sheets, labels, equipment manuals, tool box, etc.).

### Selection of Sampling Equipment

The collection of water samples requires the use of a variety of sampling equipment depending on the

station, the medium to be sampled, and the water quality parameter list. The choice of sampler type must be closely related to the parameter list in order to avoid sample contamination. In addition to being parameter and station specific, sampling containers must be such that they provide suitable sample volumes, and are appropriate for use in a wide variety of environmental conditions.

**Sample bottles** Sample bottles are generally provided by the analytical laboratory. The selected bottles (including the liners and caps) must be free of contamination and suitable for the water quality parameters to be analyzed. **Table 1** gives a description of the recommended containers for specific water quality parameters, and also outlines the bottle washing and preparation procedures used for ensuring the cleanliness of the sample bottles. The volume of sample required depends on the type and number of parameters to be analyzed, the analytical method, and the expected concentrations of the parameters in the water.

**Table 1** Recommended containers and washing procedures for selected water quality parameters

<i>Parameters to be determined</i>	<i>Recommended container</i>	<i>Washing procedure</i>
Physical parameters	1 l polyethylene bottle	Rinse three times with tap water, once with chromic acid, three times with tap water, once with (1 + 1) nitric acid, and then three times with distilled water in the given order
Major ions		
Nitrogen: $\text{NO}_2/\text{NO}_3$		
Nitrogen: $\text{NH}_3$		
Nitrogen, total		
Dissolved organic carbon		
Dissolved inorganic carbon		
Suspended solids	2 l polyethylene bottle	Same as for physical parameters
Phosphorus, total	0.5 l glass (Soivrel) bottle	Rinse three times with tap water, once with chromic acid, three times with tap water, once with (1 + 1) nitric acid and then three times with ultrapure distilled water, in the given order
Metals, extractable	0.5 l polyethylene bottle	Rinse three times with tap water, once with chromic acid, three times with tap water, once with (1 + 1) nitric acid and then three times with ultrapure distilled water, in the given order
Chromium, total	0.25 l polyethylene bottle	Same as for metals but chromic acid is not used
Mercury	0.125 l glass (Soivrel) bottle	Rinse three times with tap water, once with chromic acid, three times with tap water, once with (1 + 1) nitric acid and then three times with ultrapure distilled water, in the given order
Organic toxic chemicals	1 l or 4 l glass (amber) bottles with cap lined with polytetrafluoroethylene (PTFE)	Rinse three times with tap water, once with chromic acid, three times with organic free water, twice with washing acetone, twice with pesticide grade hexane, and dry the uncapped bottle in a hot air oven at 360°C for at least 1 h
Urea	1 l glass (amber) bottle	Same as for organic toxic chemicals

Recommended sample containers, washing, and preparation procedures associated with the collection of suspended-sediment and bottom-sediment samples are outlined in *The Sampling for Water Quality Manual*.

Prior to sampling, every bottle (or sample container) should be rinsed twice with the water to be sampled. During the rinsing process, bottle caps should be put on loosely to ensure adequate rinsing of the cap, liner, and bottle threads. If replicate samples are taken, every set of bottles should be rinsed twice and then filled, one set after the other (i.e., sequentially).

Proper labeling of the sample bottle is necessary to avoid possible mistakes and confusion when the sample arrives at the laboratory. All sample and subsample containers must be affixed with a strip of vinyl labeling tape when the containers are warm and dry. Information such as the station number (station identification), sampling date and time, water quality parameter(s) to be analyzed, and the program submitter identification (Sub. ID) must be clearly printed on each container with a water-proof fine-tipped nylon marker. Bottles designated for blank samples should be similarly identified using a special code or number that has been reserved for the identification of field blank samples.

## **Water Quality Sampling**

### **Sample Representativeness**

For new sampling programs, pilot projects should be conducted to resolve logistic problems and implement procedures that would support the objectives for reaching the program goals. This should include an evaluation of each collection site by investigating temporal and spatial homogeneity. Also, the collection frequency for priority variables, sample size, preservation effectiveness, shipping efficiency, and minimization of contamination risks could be determined or checked at this stage. In addition, proper sampling techniques must be used to ensure that a sample is representative of the flow in the sampled cross-section.

The number of verticals to be sampled in a cross-section should relate primarily to the collection of a representative sample and secondarily to the volume of the sample required. If field measurements of specific conductance, temperature, pH, and dissolved oxygen show the water to be well mixed, then a sample obtained at a single vertical near the centroid of the flow may be assumed to be representative of the total flow.

*In situ* measurements of pH, temperature, specific conductance, and dissolved oxygen should be taken before actual water samples are collected, to minimize the effects of water column disturbance caused by the lowering and raising of the sampling apparatus. This is particularly important in the case of residence time waterbodies, and during periods of ice cover when the vertical distribution of many parameters may be highly variable. Once the *in situ* measurements are conducted, water samples may be collected, starting at the surface and proceeding down through the water column if applicable. Collection of sediment samples should be performed after all water column samples have been taken.

Special considerations are required for groundwater sampling. Groundwater vulnerability to contamination is affected by water depth, recharge rate, soil composition, topography (slope), as well as other factors such as the volatility and persistence of the analytes being determined. In planning groundwater sampling strategies, knowledge of the physical and chemical characteristics of the aquifer system is necessary (but almost never known). Groundwater presents special challenges for obtaining representative samples.

Samples that are to be collected for suspended sediment, or samples to be analyzed for total constituents should be collected by using approved and properly treated water-sediment depth-integrating samplers. Suggested instances where use of these samplers are not required are as follows:

1. Extreme low flow where use of the sediment sampler is impractical. Samples may be collected by immersing the bottle by hand.
2. Flood conditions when the velocity of flow is so great that the sampler (sampling apparatus) cannot be lowered.
3. Samples collected for dissolved chemical constituents that are well mixed within the sampled cross-section.
4. The necessity for aseptic collection techniques for bacteriological samples. Consequently, these samples can be collected at a single vertical near the centroid of flow, or by immersing the sample bottle by hand (when the water source is shallow).

In sampling for suspended sediment, cross-section samples should be obtained at every opportunity, using either the equal discharge increment (EDI) or equal width increment (EWI) method to obtain cross-section coefficients to apply to the point samples obtained by the sampler.

## Automatic Sampling

In many instances, particularly in accessible remote areas, automatic samplers are used effectively. In comparison to manual sampling, automatic sampling can be more cost effective at remote sites. The cost effectiveness is closely linked to the instrument's reliability, improved capabilities, and greater sampling frequency ability.

For the efficient and effective use of an automatic water quality sampler, flow data should be available at every sampling station where the sampler is used. Flow data can provide a sound basis for interpretation of water quality results. Unfortunately, automatic samplers are limited in their application. The sample handling procedures required in quantitative measurements for a wide range of water quality parameters (nutrients, major ions, total metals, toxic organics, etc.) make it virtually impossible to use automatic sampling for detecting and measuring parameters other than dissolved oxygen, pH, specific conductance, temperature, color, and turbidity.

Samples collected at remote sites by automatic samplers should be retrieved at the earliest possible time. Samples collected in this manner should be analyzed only for constituents that do not require on-site preparation and could be assumed to be representative of the associated flow event.

High concentrations of suspended solids and floating materials can limit the performance of automatic samplers and reduce the accuracy of the measurements made. Suspended sediment samples collected by automatic samplers should be analyzed individually, and the specific conductance should be measured for each sample. This helps to determine the sample representativeness of the individual samples.

Periodic manual sampling should be conducted to verify the accuracy and representativeness of results obtained from automatic samplers, and in selecting these instruments for limited water quality monitoring, attention must be paid to such factors as:

- the range of intended use;
- the level of accuracy desired;
- the skill level required for installing and servicing the automatic sampler;
- mechanical reliability of the sampler;
- adaptability of the sampler to varying weather patterns and flow regimes; and
- cost of the sampler.

## Sampling for Specific Parameters in Specific Matrices

**Toxic chemicals in water** Many pesticides and heavy metals are toxic to aquatic life even when

they are present in low concentrations. The toxicity of a particular substance is dependent to a large extent on other water quality characteristics such as temperature, pH, alkalinity, and dissolved oxygen. The complex nature of toxic chemicals (particularly trace organic toxic chemicals) demands the application of a number of QA/QC efforts which are additional to those generally used for less complex substances.

Although this section will focus on trace organic toxic chemical sampling, preservation, and analysis, the protocols and procedures that are outlined can be applied (with less complexity) to trace inorganic toxic chemicals.

In the toxic chemical monitoring programs, water, bottom sediments, fish (forage and predator), and other biota samples are collected and analyzed.

**Toxic organic chemicals** Sampling for toxic organic chemicals in water is conducted in a manner similar to any other type of water sample collection. Normally, 4 l amber glass bottles with PTFE-lined caps are used, and rinsing of these bottles in the field is not required. Sample preservation is carried out using the procedures listed in Table 2.

Recently, a number of improved field QA/QCPs have been instituted by Environment Canada with regard to toxic chemical survey projects. These procedures include the following:

- preparation of field blanks;
- preparation of spiked field blanks;
- preparation of spiked field samples (often in replicates);
- sequential replicate sampling; and

**Table 2** Procedures used for the preservation<sup>a</sup> of water samples collected for toxic chemical analyses

<i>Parameter</i>	<i>Preservation</i>
Pesticides	Add 200 ml of hexane per 4 l ample
Organochlorine	(in a 4.5 l amber glass bottle),
Organophosphorus	shake well and deliver to the
Polyaromatic	laboratory as soon as possible.
hydrocarbons	Place a piece of aluminum foil over
Polychlorinated	the mouth of the bottle before
biphenyls	screwing on the cover (except
	when there are PTFE liners in the
	cap).
Chlorophenols	Adjust to pH 4 with 25% H <sub>2</sub> SO <sub>4</sub>
Carbamates	Adjust to pH 3 with 25% H <sub>2</sub> SO <sub>4</sub>
Chlorobenzenes	Add 50 ml of hexane per 1 l and shake
Triazines	Adjust to pH 8 with 0.1 mol l <sup>-1</sup> NaOH,
	add 200 ml of methylene chloride
	(dichloromethane) per 4.5 l sample
	and shake

<sup>a</sup> All samples are kept as cool as possible in the field.

- preservation of spiked blanks and samples a few hours after spiking, to permit prolonged interaction between sample matrix and spiking solution.

In the preparation of a field blank, distilled deionized water is first added to a sample bottle prior to the field trip. The appropriate preservative is then added to the water blank in the field at the same time as the collected samples are being preserved. The resulting blank is called a field blank. The field blank is used to check on (1) the cleanliness of sample containers; (2) random field contamination; and (3) the purity of added preservatives.

In addition, solvent blanks are also run during the analytical determinations in the laboratory.

Prior to its use in the blanks' preparation, the distilled or deionized water should be checked for its purity in the laboratory. It is possible that the water may require some treatment (solvent extraction, filtering through XAD-type resin columns, etc.) before it is suitable for the required use.

Preparation of spiked field blanks is also required to check on the recovery of a spiked analyte of interest in a 'clean' matrix. Spiking solutions are prepared by laboratory personnel prior to field trips. Preparation of spiked field blanks also serves to monitor the stability of the spiking solution in a 'clean' matrix, and to check the accuracy of its preparation. The analytical results of the spiked field blanks and the spiked field samples (which are prepared at the same time in the field) are compared to see if the analytical measurement process is indicating analyte recovery at the same level in a natural sample (the presence of matrix effects) as in a blank (no matrix effects).

Spikes can be prepared by using an appropriate micro-syringe (which has been previously rinsed with solvent) to add a precise volume (generally 100 to 200  $\mu\text{l}$ ) of a spiking solution (of known concentration) to blanks and/or regular samples. All field personnel involved in the preparation of spikes should be trained in the correct use of a micro-syringe. Larger volumes of less concentrated spiking solutions may be appropriate for the preparation of spikes. This could minimize possible manipulation errors when a spiking solution is added to a sample.

Spiked samples are generally prepared in duplicate or triplicate in the field, to verify the reproducibility of spike recoveries, and to gain a better understanding of the spiking process (matrix effects, systematic errors, etc.). Replication of spikes on all occasions is recommended. Based on resource availability, duplication of spikes could be an acceptable minimum, although triplication would possibly provide more information.

The addition of preservative to spiked blanks and spiked samples should be carried out a few hours after spiking; this time delay permits physical interaction between the sample matrix and the spiking solution.

In reporting the analytical results on the spikes, both the absolute concentrations and the percent recoveries should be reported by the laboratory.

The frequency with which this set of field QA/QC samples, namely blanks, spiked blanks, and spiked samples (in replicate), should be prepared would be dictated by the water quality study or project and available resources.

Random 'sequential replicate sampling' (see below) should also be conducted regularly in addition to the above activities. Conducting sequential replicate sampling for 10–15% of all samples collected may be an adequate level of operation for a toxic chemicals QA/QC program. This sampling replication provides a means of monitoring the short-term variability of the parameters of interest. Additionally, the replication program together with information obtained from other field QA/QC samples may permit the discernment of contamination problems and/or contamination sources.

### **Extraction Techniques**

The use of liquid–liquid extraction techniques has permitted the detection of very low concentrations ( $\text{sub-ng ml}^{-1}$ ) of organic contaminants. In the extraction process, large quantities of solvent are needed for 40 l samples, and the purity of the solvent must be assured. When the 40 l sample is filtered by the extractor, the suspended solids retained on the filter can also be kept for analyses.

In the past, use has been made of Amberlite XAD-4 resin columns in the field for sample extraction of fenitrothion and aminocarb in rain water. The rain water was collected and extracted with the aid of a special sampling (collection) device equipped with Amberlite XAD-4 columns. It is possible that these types of extraction columns could have some field application in the extraction of large volumes of surface water for the determination of specific organic contaminants. However, one drawback associated with resin columns is the requirement of exhaustive cleaning with various solvents to remove all trace contaminants. Preparation of blanks, spiked blanks, spiked samples (in replicate), and sequential replicate sampling should be included as part of the specific QA/QCPs that are needed, if these Amberlite XAD-4 resin columns (or others) are used more extensively in the future.

The inclusion of QA/QCPs would assist in routinely checking the purity of the resin column(s), the cleanliness of the apparatus, the recoveries attained by the extraction and elution processes, the reproducibility of the extraction and elution efficiencies, and the representativeness of the water samples.

### Toxic Chemicals in Bottom Sediment and in Biota

The collection and interpretation of biological data present more difficulty than in the parallel cases with water and bottom sediment. Many of the organisms collected are mobile, and thus it is difficult to class them as representative of the site from which they are taken. Some water quality investigations involving biological parameters require monitoring or surveillance of an aquatic area over a long period of time. Such systematic resampling usually employs either a 'transverse' or a 'longitudinal transect' system, or a 'grid' or 'quadrant' system.

Regardless of the type or purpose of the biological sampling study, sample collection should be designed on a meaningful basis. A large number of samples collected at the wrong time or place have less value than a few samples carefully selected as to time and place of collection. The frequency of sample collection will depend on the variability of environmental and biological factors and on the study objectives. The greater the habitat variability, the more intensive the sampling program must be. Life history events of the organisms also must be considered in the design of a sampling program.

In spite of the temporal and spatial variability of aquatic populations, statistical techniques are available for the design of sampling program and for the evaluation of biological data.

In the quality assurance program for biota sampling, attempts must be made at maintaining statistically significant sample sizes for each site. In addition, where appropriate, factors such as population size, size of habitat, feeding habits, weight, sex, lipid content, and geographical disposition of habitat (relative to industrial sites, agricultural lands and developments, waste dumps and sewage inputs) should be determined to help in data interpretation.

Selection of discrete samples of the aquatic biota should be random, and the mean of five or more measurements on individual samples should be determined in order to give representative values of the parameters of interest during the laboratory analysis stage.

### Bacterial Sample Collection

Samples for bacteriological examination must be collected in bottles that have been carefully cleaned

and autoclaved for ~20 min at 121°C at 15 psi. Also glassware, except when in metal containers, may be sterilized in a hot-air oven for not less than 1 h at a temperature of 170°C. Glassware in metal containers may be sterilized at 170°C for not less than 2 h.

Bacteriological determinations should be commenced as soon as possible after sample collection, preferably within 1 h and not more than 6 h after sample collection. Samples must be chilled in ice during the time between collection and filtration. However, samples must not be subjected to freezing.

Residual chlorine in a water sample will destroy the biological population and may prevent an accurate determination of bacteria in the sample, unless the chlorine is destroyed at the time of sample collection. Therefore, if a sample from a halogenated water supply is taken, 1.0 ml of 10% solution of sodium thiosulfate should be added to the 1 l sample bottle, before sterilization in the field service unit. This reagent should neutralize ~15 mg l<sup>-1</sup> residual chlorine in the sample, and should show no effect upon variability or growth.

### Sequential Triplicate Sampling

The 'sequential triplicate sampling' program is designed to assess the efficiency and effectiveness of the overall water quality program. The program serves to evaluate whether the water sampling performed is representative; it aids in discerning contamination and/or analytical problems; and reveals problems associated with water quality data management. Overall, the sequential triplicate sampling process covers the entire quality assurance spectrum for the monitoring program by providing some information on the combination of field, laboratory, and data management components. When a problem is revealed through the use of sequential triplicate sampling, other quality control measures (field and/or laboratory) can be used to elucidate and correct that problem.

Sequential triplicate sampling may not define the exact source(s) of a problem, but can be used as an aid in determining the cause(s) of the problem.

Triplicate sampling is more effective than duplicate sampling; the use of three replicates delivers more statistical information than the use of two replicates. Higher replication (quadruplicates, quintuplicates, etc.) would be more statistically useful and significant, but the increased cost may outweigh the benefit of the potential additional information. In cases where there are very specific problems (in sampling, preservation, contamination, storage, laboratory analysis, etc.), increased repeat sampling may be deemed necessary in order to provide conclusive

experimental and statistical evidence relating to the source(s) of the problems.

In order to conduct a comprehensive evaluation of the triplicate results, it is essential first to define the acceptable degree of reproducibility between triplicate samples. One accepted rule-of-thumb is to set the maximum variation between triplicate results at a level of 10%. The arbitrary limit depends to some extent on the complexity of any or all of the stages within the monitoring program for any given parameter or suite of parameters. In the case of toxic organic chemicals, the maximum limit could possibly be extended from 10% to 20% for results at sub- $\mu\text{g ml}^{-1}$  and sub- $\text{ng ml}^{-1}$  levels or 50% or greater at or near the detection limit. However, upper parameter-based limits of variation should not be chosen in an *ad hoc* fashion, but should be consistent not only with valid and documented triplication data but also with parameter-associated operational complexities.

Table 3 presents a partial record of the results from a sequential triplicate sampling project conducted by Environment Canada in its Water Quality Data programme in the period 1984 to 1985.

#### Sample Handling, Preservation, Storage, and Transportation

Efforts must be made to minimize errors that can be introduced as a result of collecting and handling the sample. The objective is to provide the laboratory with a set of samples which closely represent the aquatic environment from which they are taken.

To ensure consistency and efficiency, sample handling (filtration, decantation, centrifugation, sample splitting, etc.), preservation, storage, and transportation procedures must be properly and accurately documented, and adhered to by field personnel.

Preserving agents should be prepared from Ultrex Grade or similar grade chemicals, and must be taken to ensure that the water sample is not contaminated by impurities residing in the added preserving agent.

In adding preserving agents to field blanks, the same level of caution exercised with actual samples must be extended to blanks. The practice of adding ultrapure distilled water to the field blank bottles in the laboratory prior to the field trip should be encouraged. The preservation of blanks can then be carried out in the field.

It is necessary to pass the water sample through a filter of specified porosity, type, and quality when a determination of the concentration of dissolved inorganic constituents has to be made. Some filters and filtration apparatus may require laboratory pretreatment and must also be rinsed with a portion of

<sup>c</sup>Median value.

Over 80% of the variations from the median values were less than 10% for the total data set, indicating the possibility for achieving substantial success with the program.

the collected sample (subsequent to rinsing with ultrapure water) before the filtrate is collected. The filtrate should be preserved (if required) by adding the proper preserving agent. The glassware utilized should be specific to the parameter that is to be analyzed. The filtering apparatus should be placed in transportation cases that permit proper storage and provide protection against shock and dirt. The transportation case can also be used as a stable work platform for filtration.

Filtration should be performed at the end of the day, to ensure the same conditions for all samples. A filtration blank for each parameter or suite of parameters should be prepared from ultrapure distilled water using the same procedure as that used for the sample. At the end of a set of filtration

runs, the glassware must be rinsed with an appropriate solution (e.g., diluted acid solution for phosphorus and metal parameters) and afterwards with ultrapure distilled water. All glassware should be rinsed with ultrapure distilled water prior to filtration and between filtration of individual samples. The glassware and filter should be rinsed by filtering the excess water, and the sample bottle used for collecting the filtrate rinsed twice with filtrate.

To prevent chemical transformation due to photo-oxidative processes and/or biologically mediated reactions, bottles containing samples should be stored in coolers during transportation. Refrigeration at 4°C should be employed for the maintenance of the quality of both preserved and unpreserved water samples. In the absence of a refrigeration unit, 'koolatrons' should be used to keep the samples cooled during transportation.

Water samples must be well stoppered and packed, to prevent spillage and/or breakage. Labels bearing the sample identification, destination, and the word 'FRAGILE' must be attached to each container. The top of the carton must be clearly identified as 'THIS END UP', and the containers in a shipment must be numbered.

A careful check must be made to ensure that all samples recorded on the field sampling sheets have been placed in a given carton, before shipping is effected. The shipping date and mode of transport must be indicated on the field sampling sheet (Figure 1).

Samples from any one location should be kept together, except in cases where all bottles of one size must be shipped together because of container size. When samples from one station must be separated and placed in more than one carton, a copy of the field sampling sheet pertaining to the bottles must be enclosed in each box.

### Chain of Custody

Complete records must be kept of every transfer of data or samples to an individual, laboratory, or storage facility. Such records will permit an investigator to determine who had custody of the material and where it was at any given time. Custody documentation is part of the support data and should be available for review by an independent auditor.

Transfer documents must be updated and maintained at a central location such as in the office of the program or project manager. These records are of great importance in establishing the validity of any questionable data.

Chain of custody procedures must assure that:

1. Only authorized personnel handle the sample.
2. Only the field sampling techniques specified for the measurement program are used.
3. A record tag is attached to the sample immediately after collection, and the tag should include the following information: program or project identification; sample field number; location; depth; collection date; time; and collector.
4. Blank samples with and without added chemicals (preserving agents) are interspersed with the actual samples.
5. All record forms are completed.
6. The transfer of samples is documented.
7. Transfer procedures provide for proper protection and preservation. For example, if samples are mailed they should be sent by certified mail with a request for an acknowledgement of receipt.

### Field Safety

Safety procedures and guidelines affecting every phase of the sampling operation must not only be documented, but must be enforced if accidents and hazardous conditions are to be avoided.

All field personnel must have a copy of the field safety manual which gives the procedures and precautions to be observed during the collection of water samples, and personnel must be provided with the appropriate safety equipment (protection hat, boots, float-jackets, security belt, etc.)

Brochures, documents, and books relating to field safety, laboratory safety, occupational health and safety, hazardous chemicals, and transportation of dangerous goods should be made readily accessible and available to all field personnel. A copy of each document should be kept in the sampling vehicle or the mobile laboratory.

### Field Audit Program

Performance and systems audits must be instituted and should become stable and continuing features in the field QA/QC program.

The systems audit should consist of a review of the total data production process, which includes on-site reviews of the field's operational systems, the physical facilities for sampling, sample handling, storage, transportation, and the measurement protocols.

The audit system should be used as one of the channels for detecting, flagging, and correcting errors or defects at any point in the field QA/QC process.

Guidelines in the audit program should specify who will conduct the audit, what protocols and procedures will be used, and to whom the audit reports

will go. A number of procedures for conducting an audit program for laboratory operations have been proposed. These procedures and guidelines are easily adaptable to the field sampling and testing operations, since there is a similarity in the mechanics of

both types of program (e.g., constructing the audit team; planning prior to the audit; developing audit methods; subjective and objective measurement procedures; evaluating and assessing the audit findings; and using the audit report to effect change).

### Training on Quality Assurance in the Laboratory

Professional training on the subject of quality and particularly on accreditation, is fundamentally important. Background training centered on aspects such as the basic concepts, objectives, and advantages of QA and the QC system, as well as on the requirements laid down in the applied Standard(s), helps in acquiring and developing skills, attitudes, and performance, and is therefore highly relevant for the success of an action plan or work plan leading to the laboratory accreditation. In addition to focusing on quality aspects, it is essential to identify what type of background training is required by different staff members in all of the technical aspects which have to be implemented within the scope of the accreditation process, such as instrument calibration, method validation, uncertainty calculations, data validation, result trend analysis, etc.

### Laboratory QCPs

QCPs are the means by which a quality assurance program (QAP) is implemented. A QAP is usually divided into two classifications, namely the intralaboratory (in-house) and interlaboratory (between laboratory) quality control programs. The former program is a continuing and systematic regime carried out by each individual laboratory. Unless several appropriate standard reference materials are available for the specific parameter, substrate, sample matrix, and concentration levels under study, an in-house QAP can only reflect the performance of each laboratory in isolation. In order to assess and/or ensure the reliability and compatibility of sets of data generated by different laboratories, an interlaboratory QAP is necessary in addition to the intralaboratory QAP.

QCPs are intended to make available to analysts a standardized approach for minimizing analytical errors and to provide the assurance of the generation of good data with the best possible precision and accuracy. This is achieved by integrating into normal laboratory practices steps which would ensure freedom from sources of error such as contamination, matrix effects, human and instrumental bias and random errors, fluctuating instrumental sensitivity, and discrepancies in analytical standards.

#### Intralaboratory QCPs

The intralaboratory quality control program consists of a number of appropriately defined procedures. For every batch of analyses for water quality samples, the

following steps should be followed:

- Before deciding to use an analytical standard, a cross check should be made with standards of other manufacturers to determine purity and/or compatibility.
- Run an appropriate reagent blank to check for contamination.
- Spike reagent blanks at various levels of concentration to check the performance of the analytical instrument.
- Spike about every tenth sample with a concentration of analyte similar to that found in the natural sample. This step checks for matrix interference effects and determines recovery.
- If matrix interference is encountered, use the method of 'standard additions' to calculate the concentrations of analyte.
- In order to check the performance of the overall procedure, prepare synthetic samples at various concentration levels. Matching the sample matrix gives added information to the analyst.
- 'Close bracketing' of standards should always be exercised in order to check on changes in sensitivity. This involves running a standard about every tenth sample, as well as running the complete calibration graph before and after the samples.
- To determine the precision of  $n$  replicates of one sample, analyze 10 or more aliquots from a given sample, and use the formula given in eqn [5].
- Run a replicate of about every tenth sample to check the precision of the system. Use the formula for paired determinations to calculate the precision (eqn [6]).
- If available, run one or more certified standard reference materials (CRMs) to check the accuracy of the overall method (use eqn [7]).
- Run secondary in-house reference materials (control samples) in order to further check on recovery. Due to the limited supply and high cost of CRMs, in-house reference standards (control samples) should be used. They are also useful in the preparation of 'quality control charts'.
- For parameters determined routinely, quality control charts provide a powerful tool to establish control of the analytical system. This technique should be used whenever feasible.
- If difficulty is encountered in drawing the analytical calibration curve by the free-hand technique, use the 'method of least squares'.

**Precision** Precision or reproducibility describes the degree of closeness of agreement between the data generated from replicate or repetitive measurements by applying the same experimental procedure several

times under prescribed conditions. Statistically the concept is referred to as dispersion and it measures the variability of the analytical method resulting from random errors. Precision is generally reported as the standard deviation (SD) or relative standard deviation (RSD). The precision of an analytical method has two components which should be recorded for each method:

1. The within-run precision ( $SD_w$ ) measures the random error during processing of a single batch of samples analyzed at the same time.
2. The between-run precision ( $SD_b$ ) measures the variability between various batches of samples analyzed.

The precision of a method is ordinarily measured by the SD, where SD is defined as

$$SD = \left[ \sum (X_i - \bar{X})^2 / (n - 1) \right]^{1/2} \quad [5]$$

where  $n$  is the number of replicate results of the sample,  $\bar{X}$  is the mean of  $n$  determinations, and  $X_i$  is the value of the  $i$ th determination.

In the case where SD is independent of concentration (i.e., SD is constant for a given range of concentration), results of duplicate analyses of different samples may also be used to calculate the precision. In such a case:

$$SD = \left[ \sum (x_i - y_i)^2 / (n - 1) \right]^{1/2} \quad [6]$$

where  $x_i$  and  $y_i$  are  $n$  paired sets of duplicate analysis results of different samples (relating to the same parameter of interest).

Often precision is expressed relative to the concentration level at which it was determined. This term is called % relative standard deviation (%RSD) or coefficient of variation (cv), and is defined as  $100 SD/\bar{X}$ .

**Total precision** In the analysis of water samples, cyclic replication (e.g., triplication) at sampling sites is used in an attempt to identify contamination problems as well as sampling errors. To distinguish between the errors occurring in the field and those occurring in the laboratory, repetitive testing is conducted in the laboratory on replicate samples and single samples. It is then possible to extract the field 'component error' from the total error, using the following approximate equation:

Field precision

$$\approx \frac{\text{total precision}}{(\text{replicate samples})} - \frac{\text{Laboratory precision}}{(\text{repeats per sample})}$$

A sample subdivided in the field and preserved separately should be used whenever possible, to assess the variability of sample handling, preservation, and storage along with the variability of the analysis process. If the nature of the matrix, the sample acquisition procedure, or the analytical technique prevents the assessment of the entire measurement system, the replicate samples used to assess precision should be selected to incorporate as much of the measurement system as possible.

**Precision and concentration** Frequently the precision of a method is not constant over the concentration range of interest. When the precision varies significantly with concentration, a plot of precision versus mean concentrations should be made in order to describe or determine the concentration dependence. If the precision varies curvilinearly with the concentration level, a graphical plot should be presented with the equation for the graph included.

**Accuracy** Accuracy refers to the correctness of the data and defines the degree of agreement of the measurements with the true value of the magnitude of the quantity concerned. Inaccuracy results from imprecision (random error) and bias (systematic error) in the measurement process.

The accuracy of a determination is expressed as % Error as follows:

$$\% \text{ Error} = (\bar{X} - X_{SRM}) \times 100 / X_{SRM}$$

where  $\bar{X}$  is the mean value of replicate determinations of a standard reference material, and  $X_{SRM}$  is the certified value of the standard reference material.

In the absence of CRMs it is possible to estimate the accuracy by determining the 'spike recovery' of a given parameter. During method validation, spike recovery is established by spiking the analyte into an appropriate matrix at a minimum of three levels which span the range of interest. Since this procedure introduces the analyte in the soluble form, the recovery does not account for extraction efficiency from solid matrices such as sediment and biological tissue or from suspended and colloidal matter in liquid samples. Recovery is calculated on a percentage basis as follows:

$$\% \text{ Recovery} = (C_{\text{found}} - \bar{C}_{\text{blank}}) \times 100 / C_{\text{added}}$$

where  $C_{\text{found}}$  is the measured concentration in the sample,  $\bar{C}_{\text{blank}}$  is the average concentration of the blank, and  $C_{\text{added}}$  is the known concentration added to the sample.

Recovery can also be monitored by spiking at least 10% of the actual samples and calculated by the

equation:

$$\% \text{ Recovery} = (C_{(\text{sample}+\text{spike})} - \bar{C}_{\text{sample}}) \times 100 / C_{\text{added}}$$

where  $C_{(\text{sample}+\text{spike})}$  is the measured concentration in the spiked sample,  $\bar{C}_{\text{sample}}$  is the average concentration of the unspiked sample, and  $C_{\text{added}}$  is the known concentration added to the sample.

**Accuracy and concentration** As with precision, the accuracy of a method may not be constant over the concentration range of interest. When a significant concentration dependence is observed, it can be reported by either a linear slope and intercept, by an alternative functional relationship, or by a graph or table.

### Interlaboratory Quality Control

Interlaboratory quality control studies are designed to determine the degree of compatibility of the data generated by participating laboratories. Furthermore, such studies help to determine interlaboratory precision and accuracy and to standardize analytical methodology. They also provide valuable data for the certification of standard reference materials.

A well-designed multisample interlaboratory quality control program provides:

- The necessary documented information to data users on the overall competence and proficiency of a laboratory through time in providing data to costly technical, environmental and health programs.
- Confidence to correlate and present future data sets from a single or different laboratory since the interlaboratory levels of confidence through time can be established.
- A neutral evaluation of the effectiveness of in-house QCPs and early warning to the operational laboratories.
- A vital mechanism to spot bias in the laboratory measurement process that is undetected in intralaboratory QC.
- Quantitative measurement of systematic bias (through the use of a series of well-designed CRMs).
- A valuable database to compare different analytical systems for the same parameters.
- Realistic criteria for acceptability of data.

### Intralaboratory and Interlaboratory Precision

For analytical procedures, precision may be specified as either intralaboratory (within-laboratory) or interlaboratory (between-laboratory) precision. Estimates

of intralaboratory precision represent the agreement expected when the same laboratory (or operator) uses the same method to make repeated measurements on the same sample. Interlaboratory precision refers to the agreement expected when two or more laboratories (or operators) analyze the same or identical samples with the same or different methods. Intralaboratory precision is more commonly reported; however, where available, both intralaboratory and interlaboratory precision should be listed in the data compilation.

At present, there is no completely valid method available to directly calculate the interlaboratory precision from the intralaboratory precision or vice versa. This is unfortunate because frequently only one type of precision estimate is available for a method. However, in general, the following comments are applicable. First, the intralaboratory precision should be smaller than the interlaboratory precision because of additional variables in the latter. Second, if the interlaboratory precision is much larger than the intralaboratory precision, this indicates that the method is very technique-sensitive. Such information can be very important when considering a project that might involve several laboratories analyzing the same sample.

A semi-empirical formula that is useful in relating the intralaboratory precision with the interlaboratory precision is represented by the following relationship:

$$S_B = [S_{\bar{x}}^2 - S_w^2/N]^{1/2} \quad [7]$$

where  $S_w$  represents the within-laboratory precision,  $S_B$  represents the between-laboratory precision,  $S_{\bar{x}}$  denotes the overall standard deviation, and  $N$  is the number of replicate observations or measurements used for finding the average (mean). The following example illustrates the relationship between  $S_w$  and  $S_B$ .

The data for a water quality sample containing arsenic as tested at three laboratories are as shown in Table 4. Assuming that the three standard deviations are estimates of one and the same population standard deviation, it is quite proper to 'pool' the variances, and take the square root of the pooled variance. Using this procedure, the best estimate of the within-laboratory standard deviation ( $S_w$ ) is obtained as

$$S_w = \{\frac{1}{3}[(1.01)^2 + (1.22)^2 + (0.51)^2]\}^{1/2} = 0.961$$

If the standard error of the mean,  $S_{\bar{x}}$ , is found for the three averages 67.45, 66.75, and 65.95,

**Table 4** Arsenic concentrations in a water quality sample

Laboratory no.	Reported concentrations	Average concentration	Standard deviation
1	66.1 68.5 67.4 67.8	67.45	1.01
2	68.4 66.1 66.9 65.6	66.75	1.22
3	65.2 66.1 66.3 66.2	65.95	0.51

we obtain

$$S_x = \left\{ \frac{1}{2} [(67.45 - 66.72)^2 + (66.75 - 66.72)^2 + (65.95 - 66.72)^2] \right\}^{1/2} = 0.751$$

If the laboratories displayed no systematic differences, the standard deviation that has been calculated from the averages (of four replicates) should be equal to  $S_w/\sqrt{4}$ , and

$$S_w/\sqrt{4} = 0.961/\sqrt{4} = 0.486$$

The fact that the calculated value of  $S_x$  is larger than  $S_w/\sqrt{4}$  can be explained only through the presence of an additional component of variability. This component, which is the between-laboratory variability ( $S_B$ ), is calculated by subtracting the anticipated  $S_w^2/N$  from the observed variance  $S_x^2$ , and taking the square root. That is,

$$S_B = [(0.751)^2 - (0.486)^2]^{1/2} = 0.573$$

In general, if  $S_x$  and  $S_w$  are known, then  $S_B$  can be easily calculated using the formula of eqn [7].

### Detection Limits

The limit of detection (LOD) is one of the most important terms used for comparing various analytical procedures, techniques, or instruments. It is defined as being the lowest concentration of the analyte that can be distinguished with reasonable confidence from the blank or background. In water quality laboratories the confidence level of 95% is adopted as a standard for LOD for all analytes.

Different statistical approaches are reported in the literature to calculate limits of detection. The LOD for a determinant can easily vary through the use of

different statistical approaches. This problem is well documented in the literature.

The LODs can be represented in three different forms depending upon the requirements. The three representations are (1) the instrument detection limit (IDL), (2) the method detection limit (MDL), and (3) the practical detection limit (PDL).

**Instrument detection limit (IDL)** The IDL is the lowest concentration of analyte that an analytical instrument can detect and which is statistically different from the response obtained from the background instrumental noise. The IDL is established by adding the analyte in reagent (blank) water or appropriate organic solvent to give a final concentration within five times the estimated IDL and calculating the standard deviation by introducing the solution directly into the instrumental system to obtain seven or more replicate measurements. The IDL is then calculated using the 95% confidence level as follows:

$$IDL = t_{(n-1)} \times SD \quad \text{for } n \geq 7$$

where  $t_{(n-1)}$  is the value for a one-sided Student's  $t$ -distribution for  $n - 1$  degrees of freedom.

The IDL should be used to indicate the absolute LOD of the analytical technique and/or instrument.

**Method detection limit (MDL)** The MDL is the lowest concentration of analyte in distilled and/or deionized water that a method can detect reliably and is statistically different from the response obtained from a blank carried through the complete method including chemical extraction or pretreatment of the sample. When the MDL is experimentally evaluated for each matrix by the analysis of samples or spiked samples, then the PDL is determined (see below).

When repeated analyses of blanks show a positive response for the analyte, the MDL is defined as:

$$MDL = \bar{S}_b + t_{(n-1)} \times SD$$

where  $\bar{S}_b$  is the average signal (or level) for the blanks,  $SD$  is the standard deviation of the replicate determinations, and  $t_{(n-1)}$  is the one-sided Student's  $t$ -distribution for  $n - 1$  degrees of freedom at a confidence level of 95%.

**Practical detection limit (PDL)** The PDL is the lowest concentration of analyte in a real sample matrix that a method can detect reliably and is statistically different from the response obtained from a blank

carried through the complete method. It is calculated in the same manner as the MDL above.

For a specified method and analyte, the PDL will vary with different sample matrices since these may affect reproducibility, blanks, and interference levels. It is always  $\geq$  MDL.

**Limit of quantification (LOQ)** The LOQ is defined as follows:

$$\text{LOQ} = \bar{S}_b + 10 \text{ SD}$$

where  $\bar{S}_b$  is the average signal (or level) for the blank and SD is the standard deviation of the replicate determinations. This defines the level above which quantification is reliable and also a region between the MDL and the LOQ, where detection is reliable but quantification is not. The LOQ is the level above which quantitative results may be obtained with a specified degree of confidence.

### Reporting of Analytical Results

In no case should the term 0 (zero) be used to report an analytical result. In all cases for which no analyte was detected, the notations 'ND' (none detected) and 'L' (less than) should be used to report the result. The value following L is the MDL. For example, L 0.001 means that the analyte has been determined at a level less than the MDL of  $0.001 \mu\text{g ml}^{-1}$  (if the unit of measurement is in  $\mu\text{g ml}^{-1}$ ). If the result falls between the MDL and the PDL, the value may be reported in parentheses, with an explanation that the result is less than the PDL and the recovery and precision have not been evaluated at that level.

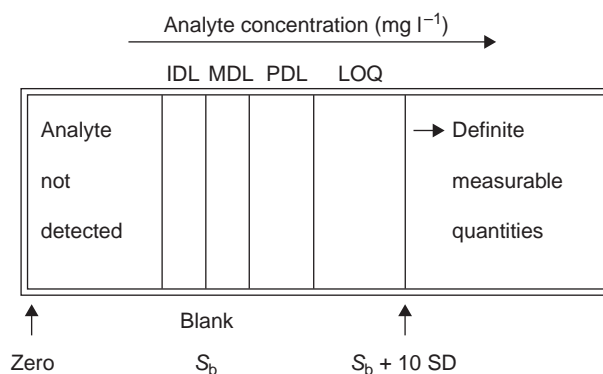

In some cases, data and analyte recovery or concentration may be reported down to instrumental detection limit values (left-censored data) provided that the necessary explanation accompanies the results, and indicates changes in sample size, final aliquots prior to analysis, or method quantification including the use of internal standards or surrogates.

Figure 2 shows a graphic summary in which the IDL, MDL, PDL, and LOQ are interconnected.

## Data Handling and Data Management

### Data Quality

The quality of data is to a large extent evaluated on the basis of their uncertainty when compared to end-use requirements. When data are accompanied by consistency, and their uncertainty is small when compared to the requirements, the data are considered to be of adequate quality. When excessively variable, or the level of uncertainty exceeds the

**Figure 2** Interconnection between IDL, MDL, PDL, and LOQ.

needs, the data may be said to be of low or inadequate quality. The assessment of data quality can thus be a relative determination. What is high quality for one situation could be unacceptable in another.

The virtue of water quality data may be assessed on the basis of two aspects: the accuracy of identification of the parameter or variable measured and the numerical accuracy. The qualitative identification must be made without reasonable doubt, and the quantitative measurements must be conducted precisely and accurately. Quantitative measurements must be made in such a manner that any error or uncertainty in the measurements can be tagged with a stated probability. To this end, measurements must be made in such a way as to provide statistical predictability.

Data quality assurance must deal with the aspects of data handling and data management shown in Table 5.

### Auxiliary Data

The practice of collecting supporting information during all phases of the measurement programs must be encouraged, and this auxiliary data must be easily available via electronic data processing facilities or field and laboratory records. The use of auxiliary data may become necessary during the data interpretation process.

The following information may be considered as auxiliary data:

- data charts and printouts;
- equipment performance records;
- calibration records;
- operation logs;
- environment conditions prior to and during sampling;
- measurement comparison records;
- quality control and system audit records; and
- records of corrective actions.

<i>Data reporting</i>	
Performance evaluation reports	Responsibility centres
Data reports	Confidentiality
Interpretive reports	Provisional reports
Data presentation	Final reports
Turn-around times	Feedback from clients and data users, <i>re</i> data reports
Report control procedures	

Auxiliary data should be collected throughout the measurement program and reviewed periodically.

Auxiliary data are important in determining the validity of the measurement program data. For example, auxiliary or support data could be used in deciding whether or not an outlier is a valid value or an artifact. Ideally, unusual conditions occurring during the field sampling and laboratory analysis operations should be recorded on the field and laboratory data reports. Failure to report such occurrences may place the acceptance of important data in jeopardy, or may lead to the rejection of that data.

### Introduction

The application of radioactive materials in analytical chemistry is based on two outstanding features of radioactivity: the ease of measurement of the emitted radiation and the possibility of using radioactive isotopes as markers for labeling chemical elements or chemical compounds. Often, higher sensitivities in analytical determinations can be achieved using radiochemical methods or nuclear techniques than applying other analytical methods. The main disadvantages of the application of radiochemical methods are related to the problems connected with the handling of radioactive materials and the limited availability of suitable radioisotopes for some chemical elements.

Radiochemical methods in analytical chemistry are used for the qualitative and quantitative determination of most of the chemical elements or chemical species, or for the location or pathway of substances

in a system under investigation. Radioactive materials are also applied for quality assurance, improvement, and development of analytical procedures. To achieve these goals, radiochemical methods have been developed and applied. In fact, even the discovery of the radioactive elements polonium and radium (1898) by the pioneering work of Marie and Pierre Curie involved the application of radiochemical methods, the application of nonisotopic carrier materials. Another radiochemical method was reported a few years later by Hevesy and Paneth (1913) in a study of the solubility of lead sulfide; they used the natural lead isotope  $^{210}\text{Pb}$  as radioactive tracer. Isotope dilution was introduced by Hahn (1923) to determine the yield for the separation of isolated protactinium-234 using protactinium-231. The technique of neutron activation analysis had been applied by Hevesy and Levi after the discovery of the neutron and the possibility of nuclear reactions to produce radioactive specimens from stable elements. In 1938, the application of radiochemical methods saw the use of nonisotopic and isotopic carriers by Hahn and Strassmann resulting in the discovery of nuclear fission. Radiochemical methods also played an important role in the research work related to transuranium elements.

During the last years radiochemical methods for routine analysis seem to have lost ground to other,

nonradiochemical methods, primarily spectrometric, but because of their reliability they are indispensable and extremely useful for the certification of standard reference materials. Therefore, they play an important role in the field of quality control and quality assurance in analytic chemistry. There is also no doubt that the modern standard of the application of short-living radionuclides in diagnostic nuclear medicine depends on the application of radiochemical methods.

The applicability of radioactive substances in analytical chemistry depends on the properties of the radioactive material (type, energy, and half-life of the radioactive atoms), the availability of the radioactive material, and the availability of suitable radiation detection methods.

Some basic knowledge of the structure and rearrangement procedures of unstable atoms, properties of radiation, characteristics of radiation detectors, and production of artificial radionuclides is helpful for the understanding of radiochemical methods and their application in analytical chemistry. Also, it has to be pointed out that for the use of radioactive materials not only do the principles of radiation protection have to be observed but also one has to follow strictly those rules that depend on the legislation of the relevant country.

## Radioactive Atoms

Atoms, whether existing in nature or artificially produced, are made up of protons, neutrons, and electrons. The positively charged protons and the neutrons, which are particles without electrical charge, form the nucleus, and with the negatively charged electrons build up the shell of the atom. The overall number of particles and the ratio of protons to neutrons are of significance to the stability of an atomic nucleus. If the nucleus is too large or if there are either too few or too many neutrons for a given number of protons, the atomic nucleus turns out to be unstable. In an attempt to reorganize itself to a stable

configuration some rearrangement processes will take place in the atomic nucleus, which are accompanied by the release of particles or electromagnetic waves or both. Such nuclei are said to be unstable. The rearrangement process is usually called radioactive decay. Until now ~2000 such types of atoms, called radionuclides, have been identified.

## Types of Radioactive Decay

The various decay processes are listed in Table 1. Radioactive nuclides emit either nucleons (alpha particles, very rarely protons or neutrons) or electrons (negatrons, positrons). As an alternative to the emission of a positron, a proton may capture an electron of the K-shell (K-capture). By the emission of an alpha particle the mass number and the atomic number are reduced; by the emission of electrons either the number of neutrons ( $\beta^-$ -decay, negatron emission) or the number of protons ( $\beta^+$ -decay, positron emission) is reduced. By K-capture also the number of protons is reduced. Due to the missing electron in the K-shell, characteristic X-rays of the newly produced atomic species are emitted.

In most cases the emission of nucleons and electrons leads to an excited state of the resulting new nucleus. The excitation energy is given off in the form of one or several gamma-ray photons. In most cases this de-excitation takes place within an extremely short period of time (less than  $10^{-12}$  s) but in some cases this transition is delayed. Such a type is called an isomeric state of a nuclide.

Some very heavy nuclides have the tendency toward spontaneous fission, they decay to two (rarely to three) smaller nuclei.

## Rate of Radioactive Decay

Although it is known that the stabilizing rearrangement or decay of an unstable (radioactive) atom will occur sometimes, it is not known precisely when this will occur. For a statistically significant number of

**Table 1** Some decay processes

Decay	Radiation	Symbol	Example	Remarks
$\beta^-$ decay	Negatrons	$\beta^-$	$^{14}\text{C} \rightarrow ^{14}\text{N} + \beta^-$	Mainly for elements with high atomic number ( $Z > 83$ ) $\sim 10^{-12}$ s after $\alpha$ or $\beta$ decay excitation energy is given off
$\beta^+$ decay	Positrons	$\beta^+$	$^{11}\text{C} \rightarrow ^{11}\text{B} + \beta^+$	
Electron capture	Characteristic X-rays	$\epsilon$	$^{85}\text{Sr} + e^- \rightarrow ^{85}\text{Rb}$	
Alpha decay	Helium nuclei	$\alpha$	$^{226}\text{Ra} \rightarrow ^{222}\text{Rn} + \alpha$	
Gamma decay	Photons	$\gamma$	$^{60\text{m}}\text{Ni} \rightarrow ^{60}\text{Ni} + \gamma$	Delayed giving off of excitation energy
Isomeric transition	Photons	$\gamma$	$^{137\text{m}}\text{Ba} \rightarrow ^{137}\text{Ba} + \gamma$	Mainly for very high atomic numbers (atomic mass $> 240$ )
Spontaneous fission	Nuclei	$f$	$^{252}\text{Cf} \rightarrow \text{fission products}$	

unstable nuclei the rearrangement process will occur at a definite and predictable rate. This decay rate is characteristic for the radioactive nuclide under consideration.

Let  $N$  be the number of unstable (radioactive) atoms of a given radionuclide present at any time  $t$ . The change in the number of unstable atoms  $N$  per unit of time at any moment is proportional to the number of atoms present at that moment:

$$\frac{dN}{dt} = -\lambda N \quad [1]$$

where  $\lambda$  is the proportionality constant, termed the decay constant. The number  $N$  decreases with time; therefore, the negative sign is used. The decay constant can be understood as the fraction of the number of radioactive atoms decaying per unit of time at any moment:

$$\lambda = \frac{1}{N} \frac{dN}{dt} \quad [2]$$

Equation [1] may be integrated to give

$$N = N_0 e^{-\lambda t} \quad [3]$$

where  $N_0$  is the number of atoms present at any starting time ( $t=0$ ), and  $N$  is the number of unchanged atoms remaining after a period of time  $t$ .

The rate of decay,  $dN/dt$ , is termed the radioactivity, or simply activity ( $A$ ). From eqns [1] and [2], we can obtain

$$A = \lambda N, \quad A = A_0 e^{-\lambda t} \quad [4]$$

A convenient method for describing the radioactive decay is in terms of 'half-life', which is the time required for one-half of any starting amount of a radionuclide to undergo rearrangement. At the end of each half-life interval one-half of the starting material will be left unchanged. Also, the 'activity' (the rate of decay, the number of decaying atoms per unit of time) will be one-half of the initial activity. Radionuclides may have half-lives from fractions of seconds to billions of years.

## Units of Radioactivity

The unit of activity is the becquerel (Bq), named after Antoine Henry Becquerel, who discovered the phenomenon of radioactivity. This unit is defined as

$$1 \text{ Bq} = 1 \text{ disintegration per second}$$

In some countries an old special unit of activity is still used, the curie (abbreviated Ci). This was originally

defined as the radioactivity associated with 1 g of radium. According to a formal definition agreed upon in 1964:

$$1 \text{ Ci} = 3.7 \times 10^{10} \text{ disintegrations per second}$$

## Energy of Radiation

The energies of particles and waves emitted by radionuclides have characteristic values. The energies of alpha particles, characteristic gamma and X-rays are constant or discrete; the energies of beta particles ejected by a given radionuclide vary from zero up to a certain maximum value. This is because a variable part of the energy is carried by a neutrino that is emitted together with the beta particle. As a consequence, beta particles show a continuous energy spectrum from zero to a characteristic maximum energy.

As a unit of radiation energy the electron volt (eV) is used. Radiation energies are in the region of hundreds of keV to several MeV:

$$1 \text{ MeV} = 1.602 \times 10^{-13} \text{ J}$$

## Naturally Occurring and Artificially Produced Radionuclides

### Naturally Occurring Radionuclides

The elements with an atomic number higher than 83 do not have stable isotopes: they are called radioelements.

The naturally occurring radioelements are mainly found in thorium and uranium ores. Uranium-238, uranium-235, and thorium-232 have long half-life ( $^{238}\text{U}$ :  $4.5 \times 10^9$  years,  $^{235}\text{U}$ :  $7.04 \times 10^8$  years,  $^{232}\text{Th}$ :  $1.4 \times 10^{10}$  years). Otherwise, they would not exist in nature today because some  $10^9$  years have already passed since the origin of the elements. Some of the radioactive decay products of these three long-living radioelements have much shorter half-lives, they are always newly produced by the radioactive decay of the long-living 'parent radionuclides'. The stable end products of these naturally occurring radioactive decay series are  $^{206}\text{Pb}$  (for  $^{238}\text{U}$ ),  $^{207}\text{Pb}$  (for  $^{235}\text{U}$ ), and  $^{208}\text{Pb}$  (for  $^{232}\text{Th}$ ). There was a fourth decay series in nature, which is 'extinct' now because of the rather short half-life of the parent radionuclide ( $^{237}\text{Np}$ :  $2.14 \times 10^6$  years).

There are a number of other elements that also have naturally occurring radioactive isotopes besides the stable ones. They also have very long half-lives, similar to uranium and thorium; some of them are listed in Table 2.

**Table 2** Some long-living natural radionuclides

Radionuclide	Half-life (years)	Radiation	Isotopic abundance (%)
$^{40}\text{K}$	$1.3 \times 10^9$	$\beta^-$ , $\beta^+$ , $\varepsilon$ , $\gamma$	0.012
$^{87}\text{Rb}$	$4.7 \times 10^{10}$	$\beta^-$	27.8
$^{190}\text{Pt}$	$6.1 \times 10^{11}$	$\alpha$	0.0127
$^{187}\text{Re}$	$5 \times 10^{10}$	$\beta^-$	62.6
$^{176}\text{Lu}$	$3.6 \times 10^{10}$	$\beta^-$	2.6

These natural radionuclides are not daughter products of the uranium and thorium series.

**Table 3** Some naturally produced radionuclides

Radionuclide	Half-life	Radiation
$^{14}\text{C}$	5730 years	$\beta^-$
$^{10}\text{Be}$	$1.6 \times 10^6$ years	$\beta^-$
$^7\text{Be}$	53.4 days	$\varepsilon$ , $\gamma$
$^3\text{H}$	12.3 years	$\beta^-$

All these radionuclides are produced in the atmosphere by cosmic radiation.

Some radioactive nuclides are produced continuously by nuclear reactions caused by cosmic radiation. They are listed in Table 3. Some of them are of interest because they can be used for the determination of the 'age' of a sample material.

### Artificially Produced Radionuclides

Man has artificially produced radioelements (technetium, promethium, transuranium elements) and also many radioactive isotopes of the naturally occurring elements. Thus, the natural radioactivity on the earth is to some extent increased by man-made radioactive materials. Many analytical research works focus on the determination of man-made radionuclides, their migration, pathways, and accumulation in the environment. The aim of this analytical research work is either to know about fate, pathway, and metabolism of materials or to obtain information about possible environmental protection problems.

Radionuclides are produced by nuclear reactions. These nuclear reactions can take place between highly accelerated atomic nuclei or between nuclei and nucleons (e.g., protons). To overcome the Coulomb barrier the charged nuclei or nucleons have to be provided with high kinetic energies. This is achieved by the use of accelerator systems such as cyclotrons, synchrotrons, and linear accelerators. Frequently nuclear reactors are used for radionuclide production because the uncharged neutrons

present in large amount in nuclear reactors are interact easily with the target nuclei.

By nuclear reactions nonradioactive elements can be transformed to a radioactive species to enable their sensitive qualitative and quantitative determination (activation analysis).

The yield of such a nuclear reaction, expressed by the resulting activity of the product, is given by

$$A = N_T \Phi \sigma (1 - e^{-\lambda t}) \quad [5]$$

where  $A$  is the resulting activity,  $N_T$  the number of target atoms,  $\Phi$  the flux density of particles bombarding the target per unit of time and area,  $\sigma$  the cross-section of the target nuclei,  $\lambda$  the decay constant of the product, and  $t$  the reaction time.

After the nuclear reaction, the target material frequently has to be purified to remove by-products. Then, the material is used for the production and synthesis of 'radiochemicals'. The resulting materials are used for application in nuclear medicine, research, and industry.

Radiochemicals are available from a series of companies. Usually the purchase, handling, and use are subjected to licensing procedures. Details of such licensing procedures depend on the legislation of the country and have to be strictly observed.

## Radiation Detection Methods

The radiation from radionuclides interacts with matter and causes ionization, excitation, or chemical changes. These effects are utilized in the methods of radiation detection and measurement. Among them the most commonly used effects are the ionization in gases, the interaction of radiation with semiconducting materials, the orbital electron excitation in solids and liquids, and the specific chemical reactions in sensitive emulsions.

Radiation detectors are specially designed to provide information about the type (alpha, beta, gamma, etc.), energy (radiation spectrometry), and intensity (number of particles or quanta) of the radiation. Some detectors also provide information about the spatial distribution of the radiation (nuclear imaging detectors).

There is a wide and excellent selection of literature available related to radiation detection methods in the field of radioactivity analysis.

### Gas Ionization Detectors

Gas ionization detectors consist of a gas volume in an enclosure that is either sealed or constructed in such a way as to permit a continuous flow of the filling gas. The system is equipped with electrodes. The

outer wall frequently serves as the cathode, while a wire rod, a plate, or a grid in the middle of the gas volume serves as the anode. An electric field is applied across the electrodes. Ions and electrons formed by the interaction of the radiation with the gas molecules are collected at the electrodes producing an electric current that serves as the basis for the detection of the radiation. Special types of gas ionization counters depend on the field strength created by the applied voltage. In ionization chambers the field strength is just high enough to collect all the ions and electrons created by the interaction of the radiation with the gas; in proportional counters the ions are accelerated by the higher field strength and can create additional ions (ion multiplication). In Geiger-Müller tubes the field strength is very high and an ion avalanche of maximum size is formed which is independent of the primary ionizing effect produced by the radiation and is mainly governed by the counter tube construction. The electronic response of ion chambers and proportional counters depend on the energy deposited in the gas volume by the radiation. These counters provide some information about the type and energy of the radiation. They can also be constructed as imaging detectors. Geiger-Müller counters do not provide any information about the primary ionization events, they only register the presence of radiation without any additional information.

### Scintillation Detectors

In scintillation detectors the emission of photons due to the interaction of the radiation with the detector forms the basis of detection. The photons are registered and processed by a photosensitive device like a photomultiplier. By choice of suitable scintillating materials information about the type of radiation can be obtained. The number of photons created by the interaction of particles or quanta with the scintillation material depends on the energy of the radiation, by which radiation spectrometry can be performed.

### Semiconductor Detectors

Semiconductor radiation detectors are crystals whose electrical conduction is altered by the absorbed radiation. Their operation depends on their semiconducting properties. They can provide information about type, energy, and intensity of radiation and are the most important devices for radiation spectrometry.

### Photographic Emulsions

If radiation passes through a photographic emulsion, chemical changes in the material are caused by ionization. As in normal photography these changes

can be made visible by development procedures. In a microscopic scale tracks of those particles emitted by a radioactive material can be made visible. At a macroscopic scale radioactive material being incorporated in a sample material can be localized. This autoradiographic method is therefore used for localization of radioactive spots at a chromatogram and has found wide application in biological and biochemical research.

### Instrumentation

Besides a radiation detector a monitoring or measuring set-up includes several electronic units, for example, a power unit for the supply of the high voltage, an amplifier system for the amplification of the small electric current produced initially by the detector, a timing unit for running the counting system for a predetermined time, a pulse-height analyzer to sort the incoming electronic information for radiation spectrometry, etc.

A schematic diagram of a radiation measurement set-up is shown in **Figure 1**. The information displayed in the instrument shows the number of events registered by the detector (number of 'counts'),

**Figure 1** Schematic picture of a radioactivity measurement set-up. The indication at the instrument (number of 'counts') depends not only on the intensity of the radiation (given in Bq) but also on the 'counting geometry' (shape and size of radioactive sample, distance, absorption and scattering effects, etc.). In addition, type and energy of the radiation and suitability of the detector plays an important role in the 'counting efficiency'.

which is proportional but in most cases not identical with the number of emitted particles or rays of the radioactive material and depends on the counting efficiency of the system. This efficiency refers to the number of particles or photons emitted by a radiation source related to the number of interactions registered by the counting system. To measure the activity of a radiation source in Bq, the decay scheme of the radionuclide and the efficiency of the counting system must be known. The counting efficiency depends on the type and energy of the radiation, the size and shape of the sample, the distance between the detector and the radioactive source, the absorption and scattering of the radiation within the sample and by the materials between sample, and finally also on the detector properties. Calibration of counting systems is important if absolute activities have to be determined in Bq. In the application of radiochemical methods measurements are frequently performed to compare the activity of radioactive samples. In this case the knowledge of the efficiency is not necessary but it must be kept constant for all samples to be measured during the investigation.

### Background Activity

It has to be pointed out that radioactivity is a natural phenomenon, so there is always some low-level activity detected by the counting system. This activity is due to cosmic radiation and terrestrial radioactive materials. This activity is referred to as the background. This background counting rate of a measurement system must be subtracted from the gross counting level in order to obtain the net counting rate of the sample.

### Statistics

Because of the random nature of the radioactive decay, the laws of statistics also have to be applied for the interpretation of radioactivity measurements.

A minimum number of disintegrations (counts) has to be observed for a reliable quantitative determination. Therefore, either a minimum concentration of radioactive material is necessary for a reliable measurement or a minimum measurement time to collect a statistical reliable result is necessary. Usually, results are given including the standard deviation (68% probability that the 'true value' is within the given limits). Detailed information is available in the literature about radioassay techniques.

### Activity and Mass of Radionuclides

Because of the emitted radiation radioactive materials can be detected even when they are present in

**Table 4** Some examples for the mass of 10 Bq of carrier-free radionuclides

Radionuclide	Half-life	Mass (g)
$^{99m}\text{Tc}$	6.6 hours	$6 \times 10^{-17}$
$^{131}\text{I}$	8.06 days	$2 \times 10^{-15}$
$^3\text{H}$	12.3 years	$3 \times 10^{-14}$
$^{137}\text{Cs}$	30.4 years	$3 \times 10^{-12}$
$^{14}\text{C}$	5730 years	$6 \times 10^{-11}$

very low concentrations. Because of this phenomenon and because of the problems of radiation protection the actual amounts of radioactive materials used in normal laboratory experiments are usually extremely small. The mass  $m$  of a radioactive material is given by the following equation which can be derived from the mathematical expression for the radioactive decay (see eqn [2]):

$$m = \frac{AT_{1/2}M}{N_A \ln 2} \quad [6]$$

where  $m$  is the mass of the carrier-free radionuclide in g,  $A$  the activity of the radionuclide in Bq,  $T_{1/2}$  the half-life of the radionuclide in s,  $M$  the relative atomic mass of the radionuclide, and  $N_A$  is Avogadro's number.

Table 4 gives some figures for the mass of carrier-free radionuclides with an activity of 10 Bq.

### Isotopic and Nonisotopic Carrier Materials

Because of the small amounts of radioactive materials there are special problems in handling such materials. Adsorption phenomena on surfaces, such as sample containers, may result in losses of radioactive materials. Conventional separation procedures involving precipitation cannot be carried out with materials of such low concentrations.

Because the actual amounts of radioactive materials used in normal laboratory experiments are usually very small a chemical 'carrier' is added. This is a nonradioactive isotope of the radioactive material. This allows conventional chemical operations like precipitation. Care must be taken that the carrier compound is chemically identical to the compound of the radionuclide or equilibrates with the chemical species of the radioactive material.

If a compound of a nonradioactive isotope of the radionuclide is added, this type of carrier is called 'isotopic carrier'. Later on the radioactive species cannot be recovered by chemical separation from the nonradioactive carrier material because the

radioactive species and the nonradioactive carrier show exactly the same chemical behavior.

After addition of a 'nonisotopic carrier' material (the same chemical compound of an element with similar chemical behavior of the radionuclide), the radionuclide and the carrier show the same chemical behavior only in some chemical procedures. This can be used for separation processes. Later on the radionuclide can be separated from the nonisotopic carrier material by specific chemical separation procedures and recovered as a carrier-free radionuclide. Using this radiochemical method Marie Curie discovered radium by first using the nonisotopic carrier barium and finally isolating radium from barium by separately crystallizing barium and radium bromides.

## Specific Activity

The term specific activity (activity per unit mass) is important for radiochemical methods like isotope dilution. Samples of carrier-free radionuclides have the highest possible specific activity for this radionuclide. By the addition of carrier material the specific activity is lower, the total amount of material (stable and radioactive materials) is increased, and some handling procedures, like precipitation, might be easier. The change of specific activity is the basis of isotopic dilution techniques.

## Radioactive Tracers

Tracers are materials that are used as markers to show the location of a substance or to follow the pathway of a substance in a chemical reaction or physical process. Such tracers have to show the same physical and chemical behavior in the system under observation as the material that is actually observed. Radioactive isotopes are ideal tracers for a nonradioactive isotope which has to be traced because they show the same chemical behavior like the nonradioactive material. It is the activity of the radioisotope that is monitored to follow the process under investigation. In addition, the amount of radioactive material to be added as a marker can be kept extremely small. This is of great importance if biological processes are investigated because the amount of tracer material can be kept low enough not to interfere in physiological processes. The most important assumption made in the use of radiotracers is that the radioactive material will blend in perfectly with the system under study and that the emitted radiation does not affect any components of the system.

## Isotope Dilution Analysis

Isotope dilution analysis is a quantitative analytical technique. The basis of this radiochemical method is that by chemical processing the specific activity (activity per unit mass) of a mixture of stable and radioactive isotopes is not changed.

Direct isotope dilution analysis is applied if an amount of an analyte cannot be separated quantitatively for analytical determination. A known amount of a radioactive isotope of the element of interest is added to the sample containing the analyte. Then a portion of the analyte is isolated in high purity from the sample. This separation step need not be quantitative. The mass and activity of the isolated portion are measured and used to calculate the amount of analyte in the original sample. There are several varieties known of this radiochemical method, e.g., reverse isotopic dilution.

## Radio Reagent Method

In radio reagent methods a radioactive species is used in a quantitative reaction and the change in activity of that species in the course of the reaction is measured. The radioactive species may be a labeled reagent or the analyte.

After separation from excess reagent by any suitable chemical separation method like liquid-liquid distribution, chromatography, etc., the mass or concentration of this product is determined from activity measurement.

The advantage of radio reagent methods over classical analytical techniques arises from the high sensitivity of the activity measurements that are not subject to interference by other substances. The principle of the radio reagent method can be adapted to various procedures.

## Activation Analysis

In classical activation analysis a material to be analyzed is bombarded with neutrons, charged particles, or photons (gamma-rays). By this bombardment radionuclides are produced from elements of the target material. These radionuclides can be analyzed qualitatively and quantitatively by radioassay methods. From the results and the knowledge of the nuclear reactions during the bombardment an analytical determination of the target material can be achieved. The radioactive products of the bombardment can be measured after the irradiation and the emitted types, energies, and half-lives provide information used for qualitative analysis and the radiation intensity supplies data for the quantitative composition of the material to be analyzed.

In prompt gamma-ray activation analysis the measurement is done simultaneously with the bombardment, and excited intermediates of the nuclear reactions emitting the so-called prompt gamma-rays are determined. The characteristic wavelength (gamma-energy) of this emission can be used for qualitative analysis and their intensity for quantitative analysis of the target material.

Nuclear activation methods can provide high sensitivities for many but not all elements. These methods are capable of simultaneous multielement analysis and in some cases they may be essentially nondestructive analytical methods. One of the main disadvantages is the lack of information on chemical form (speciation) of the elements in the analyte. Neutron activation analysis is the most common form of activation analysis, but charged particle and photon activation analysis methods are also applied.

## Aspects of Safety Regulations

Work with radioactive materials is subjected to licensing procedures that may differ from country to country. Therefore, it is of utmost importance to become familiar with the regulations being issued by the relevant competent authority. Governmental regulations related to radioactive materials are also subjected to changes from time to time to maintain the state of the art of radiation protection. Scientists

planning experiments with radioactive materials are advised to check always on the regulations that apply to this particular establishment before commencing work with any radioactive materials.

## Introduction

Radiochemical methods are primarily concerned with the study of radioactivity in naturally occurring radioactive materials and in other materials in which radionuclides and their compounds are produced by irradiation. The foundation of such studies is the careful measurement of radioactivity in a variety of environmental samples, food samples, radiopharmaceuticals, etc. Such measurement can be divided into two major types:

1. Measurement of systems of naturally occurring radionuclides where objectives include the identification and determination of amounts of natural

radionuclides, and the use of this information to determine the presence and amounts of related elements in samples (e.g., uranium, thorium, and potassium).

2. Measurement of man-made (artificial) radionuclides, including identification and determination of amounts (e.g., fission products, fallout, radioactive spills, and leakage from waste disposal sites or other facilities).

In practice, radiochemical methods can be divided into two groups, one characterized by high sensitivity and the other offering high speed but less sensitivity.

## Sampling, Sample Preservation, and Sample Pretreatment

Air sampling is one of the most important and difficult steps in the surveillance of air pollution. Particulate air sampling techniques include filtration, electrostatic

In prompt gamma-ray activation analysis the measurement is done simultaneously with the bombardment, and excited intermediates of the nuclear reactions emitting the so-called prompt gamma-rays are determined. The characteristic wavelength (gamma-energy) of this emission can be used for qualitative analysis and their intensity for quantitative analysis of the target material.

Nuclear activation methods can provide high sensitivities for many but not all elements. These methods are capable of simultaneous multielement analysis and in some cases they may be essentially nondestructive analytical methods. One of the main disadvantages is the lack of information on chemical form (speciation) of the elements in the analyte. Neutron activation analysis is the most common form of activation analysis, but charged particle and photon activation analysis methods are also applied.

## Aspects of Safety Regulations

Work with radioactive materials is subjected to licensing procedures that may differ from country to country. Therefore, it is of utmost importance to become familiar with the regulations being issued by the relevant competent authority. Governmental regulations related to radioactive materials are also subjected to changes from time to time to maintain the state of the art of radiation protection. Scientists

planning experiments with radioactive materials are advised to check always on the regulations that apply to this particular establishment before commencing work with any radioactive materials.

## Natural and Artificial Radioactivity

## Introduction

Radiochemical methods are primarily concerned with the study of radioactivity in naturally occurring radioactive materials and in other materials in which radionuclides and their compounds are produced by irradiation. The foundation of such studies is the careful measurement of radioactivity in a variety of environmental samples, food samples, radiopharmaceuticals, etc. Such measurement can be divided into two major types:

1. Measurement of systems of naturally occurring radionuclides where objectives include the identification and determination of amounts of natural

radionuclides, and the use of this information to determine the presence and amounts of related elements in samples (e.g., uranium, thorium, and potassium).

2. Measurement of man-made (artificial) radionuclides, including identification and determination of amounts (e.g., fission products, fallout, radioactive spills, and leakage from waste disposal sites or other facilities).

In practice, radiochemical methods can be divided into two groups, one characterized by high sensitivity and the other offering high speed but less sensitivity.

## Sampling, Sample Preservation, and Sample Pretreatment

Air sampling is one of the most important and difficult steps in the surveillance of air pollution. Particulate air sampling techniques include filtration, electrostatic

precipitation, thermal precipitation, gravitational settling, centrifugal separation, and impingement. When the concentration of the radioactive component is high, the sampling procedure is simple. An enclosed metal or glass vessel equipped with inlet and outlet valves is filled simply by passing air through the vessel and subsequently closing the valves. When the radioactive component is present at a lower concentration, it is necessary to concentrate this radioactive component during the sampling procedure by using either sorption or compression. The absorption of carbon dioxide ( $^{14}\text{CO}_2$ ) in alkali and the adsorption of radon on charcoal are examples of such procedures.

In the case of air sampling by absorption in a collecting liquid solution, it is often advantageous to extract the absorbed analytes or concentrate them on ion-exchange materials, followed by elution. It is possible to dissolve the aerosols from the collecting filters and concentrate the analytes by ion exchange or extraction. Sometimes it is necessary to combine several filters to obtain sufficient analyte for measurement.

Wet- or dry-ashing technique may be needed to prepare particulates for dissolution. Aerosols and filter media are mineralized for these techniques.

Methods for sampling can be divided into two groups. In the first, the  $\alpha$ -,  $\beta$ -, or  $\gamma$ -activity (or  $\gamma$ -spectrum) is to be measured. In the second, a radiochemical analysis for certain radionuclides is to be performed.

For direct measurement, the sample is prepared by drawing a certain amount of air through a filter. To measure  $\alpha$ - and  $\beta$ -activities, the aerosols must be retained on the filter surface. Membrane filters, plastic filters, and glass fiber filters are used. For  $\gamma$ -activity measurement, the filters need not retain the sample at the surface.

When a radiochemical analysis has to be performed, the retention of aerosols on the filter surface is not necessary, and those filters that yield only small amounts of ash are preferred. This requirement is best satisfied with cellulose filters. In addition to filtration, radioactive aerosols can also be concentrated by electrostatic or thermal precipitation.

In water sampling, close attention must be given to the type of sample, the sampling equipment, sample container, holding times, and proper preconcentration techniques. In the case of radioactive material, it is very important that they are present generally in extremely low concentrations in water, so that sorption and volatilization can occur. It has been recommended that preservatives be added at the time of sampling unless suspended and dissolved fractions are to be separated. Concentrated hydrochloric or nitric acid may be used to adjust the pH (usually to  $<2$ ). Acidified samples should be held for at least

16 h before analysis. All preservatives and reagents should be tested for radioactivity, as well as all sampling equipment and containers. Because of the extremely low concentrations of many water constituents ( $\mu\text{g l}^{-1}$ ), it is frequently necessary to concentrate samples before analysis.

Sampling of aquatic and atmospheric systems is relatively straightforward because of the basic simplicity of the sample matrix. The situation is somewhat different in the lithosphere, where there are far greater variations. Rock and minerals of greatly differing accessibility, vegetation, animals, and various fluids (including water and sludges) may be present in different sampling situations.

In the preparation of samples from biological materials, the time between sampling and analysis should be kept as short as possible. For storage times of a few (2 or 3) days, refrigeration at  $4^\circ\text{C}$  may be adequate. In favorable cases, holding times can be prolonged by the addition of chemical preservatives (e.g., formalin (formaldehyde,  $\text{HCHO}$ ) and alcohol). Dehydration (by drying, combustion, and lyophilization) is also used.

Plant materials should be carefully washed free from sands, soils, and other physical artifacts. After draining away the wash water, leaves, stems, seeds, and fruits must be dried. Undried components are homogenized with a blender with glass walls and high-quality stainless-steel blades. Dry biological samples (seeds and grains) are generally ground in mills and sieved through fine-mesh screens to obtain uniformly sieved material.

Human and animal tissues are generally cut into thin sections or ground in mills. In some cases, samples are mineralized by dry- or wet-ashing technique.

## Analysis of Natural Radioactive Materials

Naturally occurring radionuclides consist of two basic groups: primordial and cosmogenic.

Primordial radionuclides are associated with the formation of the earth. A list of these is given in Table 1. The radioactive isotopes of the elements of higher atomic numbers are members of one of four possible decay series:

Thorium series,  $4n$ :  $^{232}\text{Th} \rightarrow ^{208}\text{Pb}$   
 Neptunium series,  $4n + 1$ :  $^{241}\text{Cm} \rightarrow ^{209}\text{Bi}$   
 Uranium series,  $4n + 2$ :  $^{238}\text{U} \rightarrow ^{206}\text{Pb}$   
 Actinium series,  $4n + 3$ :  $^{235}\text{U} \rightarrow ^{207}\text{Pb}$

The neptunium series, because of the relatively short life of its parent, is no longer present in nature. The

decay sequences of the uranium, actinium, and thorium are given in **Figures 1–3**.

Cosmogenic radionuclides are produced continuously as a result of nuclear reaction in the environment, such as interaction with cosmic radiation, spallation, and natural fission. A partial list is presented in **Table 2**.

Determination is usually relative; i.e., samples are compared with standards. For comparative measurements, it may be adequate to make relative measurements without standards, with an instrument calibrated for the purpose.

Direct measurements may be complicated by the phenomenon of self-absorption, especially in the case of low-energy  $\beta$ - or  $\alpha$ -radiation. Two approaches can be used to minimize self-absorption errors:

1. Measurement of saturation layers; that is, layers that are thicker than the penetration range of the measured radiation (e.g.,  $>0.1$  mm for most  $\alpha$ -particles).
2. Measurement of infinitesimally thin layers; layers that are thin enough for self-absorption to be negligible (layers 'density'  $<0.1$  mg cm<sup>-2</sup>).

### Determination of Natural Radioactive Elements

Naturally occurring radioactive elements can be determined by measuring the activity of the appropriate radioisotopes. These measurements are particularly suitable for radioactive elements with short half-lives.

The use of radioisotopes with long half-lives is less suitable, particularly as regards accuracy and sensitivity; even in this case, however, radiometric methods are usually simpler and more rapid than conventional procedures. The basic assumption is that a radioelement has at least one isotope that can be measured; hence the isotopic composition must be known. If an element is known to have a constant isotopic composition, measurements and calculations are relatively straightforward (e.g., potassium, rubidium, samarium, lutetium, rhenium, and francium).

When an element has more than one radioisotope, determinations and data analysis are generally more complex because the isotopes may differ in half-life, especially when a series is involved, e.g., radium, thorium, polonium, radon, actinium, protactinium, and uranium. One possibility is to make measurements after the decay of the short-lived radionuclides, but this may require long waiting times. In favorable cases, it is more convenient to measure the activity of decay products (e.g., radon, thoron (<sup>220</sup>Rn), actinon (<sup>219</sup>Rn)), or correct the measurements of the short-lived radioisotopes after determination of the isotopic composition.

Emanometric methods are radioanalytical methods that use measurement of radioactive isotopes of inert gases for the determination of appropriate elements. A good example is the use of the radon isotopes <sup>226</sup>Rn, <sup>222</sup>Rn, and <sup>219</sup>Rn to determine radon, thorium, radium, and actinium. Indirect determinations

Figure 1 Uranium series decay scheme (energies in MeV).

Figure 2 Actinium series decay scheme (energies in MeV).

(e.g., use of radon to determine radium) require both components to be in equilibrium, or present in a known ratio.

In general, these methods require the removal of the inert gas from the sample; the gas is then

transferred to a suitable detector. Solid samples must be converted into liquid form such as a solution or a melt (by fusion with sodium carbonate or borax). Once the sample is in liquid form, the gas may be swept out by bubbling air through the solution into

**Figure 3** Thorium series decay scheme.**Table 2** Major cosmic-ray activated radionuclides

Nuclide	Half-life	Emission, decay	Energy of primary emission (MeV)
$^3\text{H}$	12.26 years	$\beta$	0.0181
$^7\text{Be}$	53 days	$\varepsilon, \gamma$	—
$^{10}\text{Be}$	$2.7 \times 10^6$ years	$\beta$	0.56
$^{14}\text{C}$	5730 years	$\beta$	0.156
$^{22}\text{Na}$	2.58 years	$\beta^+, \varepsilon, \gamma$	0.54
$^{32}\text{Si}$	$\sim 650$ years	$\beta$	0.1 (to $^{32}\text{P}$ )
$^{32}\text{P}$	14.3 days	$\beta$	1.71
$^{35}\text{P}$	25 days	$\beta$	0.25
$^{35}\text{S}$	86.7 days	$\beta$	0.168
$^{36}\text{Cl}$	$3 \times 10^5$ years	$\beta, \varepsilon$	0.71
$^{39}\text{Cl}$	55 min	$\beta, \gamma$	1.91, 2.18, 3.43

an evacuated ionization chamber, by passing a continuous stream of air through the sample and detector, by spraying the liquid using a small air-screw, or by shaking the liquid sample with air. An example of emanation equipment for the determination of thoron is shown in **Figure 4**. Alternatively, an  $\alpha$ -scintillation cell coupled to a photomultiplier can be used.

### Air

The natural radioactivity in air is due mainly to radioactive emanations (radon, thoron, actinon) and to those of their deposits that produce radioactive

**Figure 4** Emanation equipment for the determination of thoron: 1, purge system; 2, fritted glass disk; 3, filter with glass wool; 4, ionization chamber; and 5, electrometer.

aerosols. For the analysis of air samples, a number of approaches are possible:

1. Direct emanometric determination with large-volume (20 l) differential ionization chambers that permit measurement at activity levels of  $\sim 10^{-7} \text{ Bq cm}^{-3}$ .
2. Preconcentration of radioactive emanation by condensation, adsorption on activated charcoal, cooling with liquid air, or by sorption in cooled organic solvents (e.g., toluene or carbon disulfide). After collection, the radioactive gases can be

purged from the collectors and transferred to an appropriate ionization chamber.

3. Capture (e.g., filtration) of aerosols and measurement of their activity with scintillation counting or by autoradiography.

### Water

The concentration of natural radioactive material in water varies considerably, depending on the nature, location, and history of the water. The principal natural radionuclides are  $^{238}\text{U}$ ,  $^{232}\text{Th}$ , and  $^{235}\text{U}$  and their decay products, such as  $^{226}\text{Rn}$  and  $^{222}\text{Rn}$  from  $^{238}\text{U}$ ,  $^{228}\text{Rn}$  and  $^{224}\text{Rn}$  from  $^{232}\text{Th}$ . If we discount the presence of uranium and thorium, the contribution of which to the total activity is usually relatively small, we can differentiate between temporary radioactivity caused by radon, and permanent activity caused by radium. For the determination of radon, the emanation can be flushed to an ionization chamber and measured. Radium can be determined by  $\alpha$ -counting of a barium-radium sulfate precipitate or by measurement of  $^{222}\text{Rn}$  produced from  $^{226}\text{Ra}$ .

### Analysis of Artificial Radioactive Materials

The analysis of natural radioactive materials is relatively straightforward, since it usually involves the determination of a small number of well-known radioisotopes of a few elements. The determination of artificial radionuclides in environmental samples, food samples, radiopharmaceuticals, etc., is more complicated, because several radionuclides of a number of elements may be involved.

The first aim of the qualitative analysis is identification of all radionuclides present in a sample (identification of all activities and the nuclides responsible). The procedure has two steps:

1. The characterization of all activities present, e.g., nature and energy of radiation, relative intensities, half-life values.
2. Identification of the radionuclides responsible for the various activities.

The nature and energy of radiation can be determined by

- $\gamma$ -spectrometry with NaI(Tl) scintillation crystals or solid-state detectors such as hyper-pure germanium, germanium/lithium, or silicon/lithium systems;
- $\alpha$ -spectrometry with surface barrier detectors;

- $\beta$ -spectrometry with silicon semiconductor detectors (surface barrier or silicon/lithium type); and
- absorption measurements.

Half-life values can be determined from decay curves showing the variation of activity with time; these values must be correlated with the types of radiation found. Once this correlation has been made, appropriate tables can be used for nuclide identification.

The aim of the quantitative analysis is to measure an amount of radioactivity in either a relative or absolute sense. Common units are Becquerels (Bq), Bq per unit mass or Bq per unit volume. In special cases, the activity is expressed as a mass of the radioactive nuclide. The determination of absolute activity presents special problems in addition to those encountered in relative activity measurements. Once a source of a radionuclide of known absolute activity is available, any detector may be calibrated in terms of this standard. This calibration will be valid for other samples of the same nuclide, provided they are measured under precisely the same conditions. The calibration may also be adequate for other radionuclides emitting radiation similar to those of the standard.

The main task in the analysis of a mixture of fission products is the identification of nuclides and the determination of yields. A combination of instrumental and chemical techniques is required and the work is laborious and difficult.

One of the most hazardous fission products is  $^{90}\text{Sr}$ , because of its long half-life (28 years) and because strontium is concentrated in bone. For the determination of total radioactive strontium and  $^{90}\text{Sr}$  in water, the following procedure is used.

A known amount of strontium (as the nitrate,  $\text{Sr}(\text{NO}_3)_2$ ) is added as carrier to a water sample. The carrier, alkaline-earth and rare-earth metals are precipitated as their carbonates to concentrate the radiostrontium. The strontium is then separated from other radioactive elements and inactive sample solids by precipitation as  $\text{Sr}(\text{NO}_3)_2$  from fuming nitric acid solution, and finally precipitated as strontium carbonate,  $\text{SrCO}_3$ , dried, weighed to determine the carrier recovery, and measured for radioactivity. A correction is applied to compensate for loss of carrier and activity during the purification procedure. A delay in counting will give an increased counting rate because of the production of  $^{90}\text{Y}$ . The total activity will be due to  $^{89}\text{Sr}$  and  $^{90}\text{Sr}$ . The amount of  $^{90}\text{Sr}$  can be determined by separating and measuring its daughter,  $^{90}\text{Y}$ , after equilibrium has been reached. Counting instruments used include internal gas-flow proportional counters and thin-window proportional or GM counters. The counting systems can be calibrated with  $^{137}\text{Cs}$  standards.

**Table 3** Radiochemical procedures for environmental and food samples for various radionuclides

Analyte	Sample	Preparation, Dissolution	Chemical separation	Method of measurement
$^{24}\text{Na}$	Precipitation	Add Na carrier	Na separated by ion exchange, hydroxides scavenged, Na measured in filtrate	$\beta$ , $\gamma$ Coincidence counter
$^{14}\text{C}$	Food, air	Combust to $\text{CO}_2$	$\text{CO}_2$ purified by expansion, condensation, drying agents	Internal gas counter, anticoincidence shielded
$^{14}\text{C}$	Water	Add oxalate Carrier	C oxidized to $\text{CO}_2$ in acidic solution, $\text{CaCO}_3$ collected	$\beta$ -Counter (gas flow or liquid scintillation)
$^{32}\text{P}$	Seawater	Add $\text{PO}_4^{3-}$ Carrier	P oxidized with $\text{HClO}_4$ , $\text{NH}_4$ molybdophosphate extracted into isoamyl alcohol; precipitated as $\text{NH}_4\text{MgPO}_4$	$\beta$ -Counter
$^{131}\text{I}$	Milk	Add HCHO and I carrier	$\text{I}^-$ separated on anion exchange resin, purified by extraction; $\text{Pdl}_2$ precipitated	$\beta$ -Counter
$^{137}\text{Cs}$	Milk, bone, vegetation, ash, soil, water	Fuse with $\text{Na}_2\text{CO}_3$ or leach with $\text{HNO}_3$	Ca precipitated; Cs separated on $\text{NH}_4$ molybdophosphate, purified by ion exchange, precipitated as $\text{Cs}_2\text{PtCl}_6$	$\beta$ -Counter
$^{210}\text{Pb}$	Bone	Ignite; dissolve in HBr	Pb extracted with quaternary amine; $\text{PbSO}_4$ precipitated and counted	$\beta$ -Counter
$^{232}\text{Th}$	Bone	Ignite at $600^\circ\text{C}$	Irradiate with neutrons, dissolve in HCl, separate $^{223}\text{Pa}$ by anion exchange	$\beta$ -Counter
$^{226}\text{Ra}$	Soil, vegetation	Plant – dissolve in acids; soil – exchange with ammonium acetate	$^{225}\text{Ra}$ , $^{133}\text{Ba}$ tracers and Ba carrier added; Ra precipitated with $\text{BaSO}_4$ , separated from Ba by ion exchange; electrodeposited for counting	$\alpha$ -Spectrometry
$^{90}\text{Sr}$	Bone	Ignite, dissolve with HCl	$^{90}\text{Y}$ extracted into ethylhexyl phosphoric acid; impurities removed by amine extraction	$\beta$ -Counter
$^{90}\text{Sr}$	Food, vegetation, milk	Evaporate, ignite, fuse with $\text{Na}_2\text{CO}_3$	Sr separated, purified by nitrate precipitations, $^{90}\text{Sr}$ precipitated and counted	$\beta$ -Counter
$^{110\text{m}}\text{Ag}$	Biological samples	Grind in blender with water	Slurry treated with NaOH-AgCN solution; Ag electroplated on Pt, dissolved, AgCl precipitated	$\gamma$ -Ray spectrometry ( $4\pi$ coincidence counter)
Th-Cf	Soil	Treat with acids, fuse – KF, $\text{Na}_2\text{S}_2\text{O}_7$ , dissolve HCl	Actinides co-precipitated with $\text{BaSO}_4$ , separated by solvent extraction after adjusting oxidation states, electrodeposited for counting	$\alpha$ -Spectrometry
U	Water		Extraction into methyl isobutyl ketone	$\alpha$ -Spectrometry

Continued

Table 3 Continued

Analyte	Sample	Preparation, Dissolution	Chemical separation	Method of measurement
Pu	Soil, air particulates	Soil – ash, extract with hot HCl; particulates – ash dissolve in mineral acids or by fusion	Pu separated and purified by cation and anion exchange; electrodeposited for counting	$\alpha$ -Spectrometry
Pu	Water, air, soil, food, vegetation	Treat with mineral acids	Pu purified by anion exchange; electrodeposited for counting	$\alpha$ -Spectrometry

Fission products may contain the iodine isotopes from  $^{129}\text{I}$  to  $^{135}\text{I}$ . Of these,  $^{131}\text{I}$  is considered the most significant hazard in drinking water. Three methods are available for the determination of radioactive iodine in water samples: precipitation, sorption on an anion-exchange resin, and distillation. The precipitation method is preferred because it is simple and requires the least time. In the precipitation method, iodate carrier is added to the sample and reduced to iodide with sodium sulfite. The iodide is precipitated as silver iodide. The precipitate is dissolved, and purified with zinc powder and sulfuric acid. The iodide is finally precipitated as palladium iodide,  $\text{PdI}_2$ , for counting in a low-background  $\beta$ -counter, or  $\beta/\gamma$  coincidence system.

In the determination of transuranium elements (or nuclides), the most important step is separation of the elements from the sample matrix. Differences in redox properties are used for the separation of the first four elements in the series (neptunium, plutonium, americium, curium). Since the higher members exist primarily in the same oxidation state (III), separation by ion-exchange chromatography is commonly used. The lighter transuranic elements can be determined by common chemical methods, and trace amounts are usually determined by radiometric methods such as  $\alpha$ -spectrometry.

Ion-exchange chromatography is generally used for the separation of the transplutonium elements (americium, curium, berkelium, californium, einsteinium, fermium, mendelevium, nobelium, lawrencium). Determinations are usually made directly by  $\alpha$ -spectrometry with solid-state detectors. Some elements (americium, curium, berkelium, californium) also have long-lived isotopes and can be determined by chemical methods such as ultraviolet–visible spectrophotometry.

Illustrative radiochemical procedures for environmental and food samples for various radionuclides are summarized in Table 3.

## Radionuclide Monitoring

### Introduction

The development of applications of radioactive materials in research, industry, medicine, and agriculture, as well as the growth of nuclear power engineering programs, led to increasing amounts and varieties of radionuclides in the environment. This, together with the development of the nuclear sciences, has created the demand for proper analytical methods of monitoring radionuclides in the environment.

With the development of nuclear power engineering and nuclear technology, radionuclides, which formerly were not encountered, have entered the environment. In fact, artificial radionuclides, as well as natural radionuclides, are abundant and are introduced into the human organism in the form of food of plant and animal origin.

As a result, a new branch of science was formed to deal with monitoring of radionuclides in the environment. In a broader sense, this field involves the elaboration of relevant analytical procedures and the study of the ways radionuclides come into the environment and the health hazards they present.

From the practical standpoint, radionuclide monitoring techniques can be divided into two groups, one that is characterized by a high sensitivity and a second that offers high speed but relatively lower sensitivity. When selecting a proper analytical method, sometimes the faster method will be chosen and, other times, the more sensitive one.

### Radionuclides in the Environment

Radioactive contamination can result from either expected or accidental release of radionuclides during the treatment of uranium ores, the operation of nuclear reactors, the processing of burnt fuel elements from nuclear reactors, or the application of radionuclides in medicine, research, industry, and agriculture, as well as from radioactive fallout from the atmosphere.

Natural as well as artificial radionuclides can become sources of radioactive contamination in the environment. Primary natural radionuclides that should be considered are  $^{40}\text{K}$ ,  $^{87}\text{Rb}$ ,  $^{235}\text{U}$ , and  $^{238}\text{U}$ . Other natural radionuclides are members of

radioactive series and represent a majority of the total number of existing natural radionuclides. Radionuclides induced in nature can also be considered natural; some of these are  $\text{T}$ ,  $^7\text{Be}$ ,  $^{14}\text{C}$ ,  $^{22}\text{Na}$ ,  $^{32}\text{P}$ , and  $^{35}\text{S}$ . Artificial radionuclides that are significant from the standpoint of contamination are either direct or indirect products of nuclear fission reactions or eventually of thermonuclear processes. For example, on the average, during nuclear fission as many as 200 radioisotopes are formed of 35 different elements with medium atomic numbers. However, the abundance of many of them in the fission mixture decreases rapidly because of their short half-lives; this also leads to a rapid decrease in the total activity of the fission mixture. A regular operation of the nuclear reactor does not represent as serious a source of radioactive contamination of the environment as does the processing of burnt fuel elements. After removing fuel elements from the reactor core they are allowed to 'cool' for a certain time – 'the cooling time.' Then they are dissolved in acids. Radioisotopes of aerogens, largely of radioiodine and, in the case of an oxidation process, ruthenium (as  $\text{RuO}_4$ ), are simultaneously released. The most dangerous is  $^{131}\text{I}$ , which, after entering the atmosphere, is rapidly deposited on plants, thus contaminating the food and forage base. However, during the decomposition of burnt fuel elements, certain radioactive particles are also released, which, in spite of careful filtration, penetrate the surrounding atmosphere.

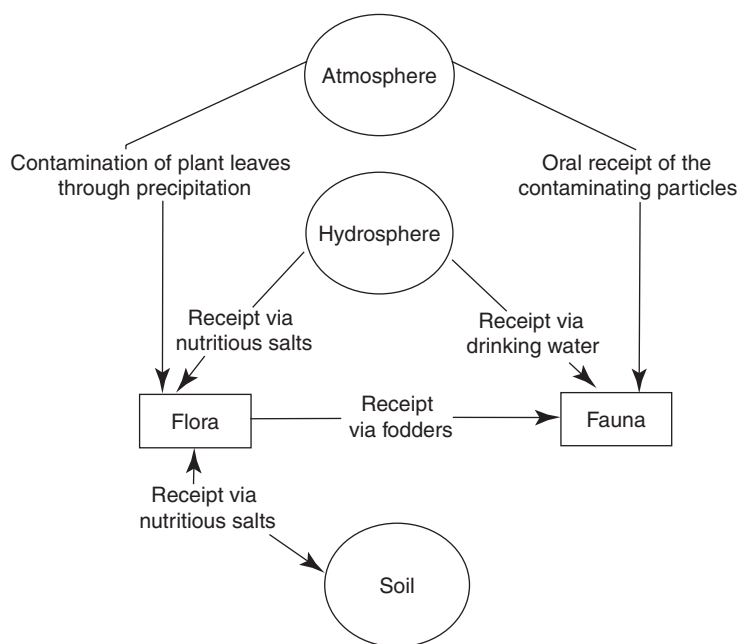

A significant amount of fission products passes into waste water. Storage of great quantities of high activity waste water is a relatively complicated problem. At the present time this is mostly solved by storage in underground tanks, concentration and conversion to solid forms, and purification by precipitation and ion-exchanging procedures.

A further source of radioactive contamination is the radionuclides induced with neutron radiation in nuclear reactors. Particularly large amounts of the following radionuclides are created:  $^{60}\text{Co}$ ,  $^{192}\text{Ir}$ ,  $^{198}\text{Au}$ ,  $^{131}\text{I}$ , and  $^{32}\text{P}$ .

From sea vessels powered by nuclear reactors,  $^{60}\text{Co}$ ,  $^{55}\text{Fe}$ ,  $^{59}\text{Fe}$ , and  $^{51}\text{Cr}$  pass into the sea with cooling water.

For the protection of man's health, studies of the contaminated biosphere, which represents a source of food, is of vital importance. Through a process that consists of several steps, mineral substances are converted to different forms of life by plants, the plants are eaten by animals, and the contaminated substances are incorporated into food. In this

**Figure 1** Radioactive contamination of plants and animals.

connection, all paths by which radionuclides pass from the atmosphere, hydrosphere, or soil to the biosphere are of interest. Some of the ways plants and animals are contaminated are sketched in **Figure 1**.

Plants can be contaminated by receiving radionuclides with nutrient solutions from water and soil. Also, soils can be contaminated by radioactive atmospheric precipitation and dust. In this way contamination is transferred to animals, since the contaminated plants are their forage. Animals can also be contaminated from the hydrosphere by drinking water.

The following essential factors should be considered when estimating radioactive contamination:

- the amount of the radionuclide;
- the character of the contamination (expected or accidental);
- the kind of radionuclide;
- the physical and chemical forms of the contaminating compound;
- the character of the contaminated area.

The nature of the contamination of the environment, as well as the degree of hazard, is given by properties of the radiation source and by the character of the contamination (whether it occurs during the usual operation of nuclear equipment or treatment of radioactive materials, or whether it results from an accident). The human organism can be exposed either directly (by inhalation, ingestion of contaminated water and/or food, or contamination of the skin) or indirectly (when contaminated materials enter into

the human organism with contaminated components of the biosphere).

The radioactivity of the environment can be measured regularly or from time to time to estimate the extent of the radiation hazard to man. Results of measuring radioactivity in samples taken from humans and from the biosphere are considered from the standpoint of maximum permissible levels based on the recommendations of national and/or international institutions. The maximum permissible levels for many radionuclides either in the whole body or in individual organs represent criteria for sensitivities for relevant radiochemical methods.

### Radioactive Contamination of the Environment

Knowledge of the composition of radioactive waste materials from nuclear equipment (regardless of their phases) is important in choosing a sampling protocol prior to any analytical procedures.

The recommendations of the International Commission on Radiological Protection (ICRP) for maximum permissible concentrations of radionuclides in air and water serve as basic criteria for determining radionuclide concentrations in air and water. For the first estimation, measurements of gross  $\alpha$ ,  $\beta$ , and  $\gamma$  activities are sufficient; however, in order to draw a responsible conclusion, individual radionuclides in the sample have to be determined.

Analysis of air holds a unique position, since air samples yield significant data about radionuclides that appear as either gases or finely dispersed particles transported by air.

Water samples come either from surface or underground water sources. Surface water can be contaminated with radionuclides either during atmospheric precipitations or in the course of the surface flow. Underground water can be contaminated with radionuclides from waste materials stored under the earth's surface; however, they may also contain natural radioactive compounds from their deposits. Some radioactive compounds are removed when surface water is conditioned for supply water; however, the most dangerous long-lived radionuclides, such as  $^{90}\text{Sr}$  and  $^{137}\text{Cs}$ , remain in the conditioned water.

Radionuclides in soil are a source of the contamination of forage and food with radionuclides, of which strontium, cesium, and radium isotopes are the most significant. Radionuclides penetrate into plants either from the atmosphere as deposits on soil surface or through roots from the soil. Plants radioactively contaminated are a significant hazard to man, either directly (food of plant origin) or indirectly (the milk of animals which receive contaminated forage).

$^{89}\text{Sr}$ ,  $^{90}\text{Sr}$ ,  $^{131}\text{I}$ ,  $^{137}\text{Cs}$ ,  $^{140}\text{Ba}$ , and  $^{226}\text{Ra}$  are found particularly often in plant materials. Of them,  $^{131}\text{I}$  and  $^{140}\text{Ba}$  represent a relatively short-term hazard, thanks to their half-lives; however, a long-term contamination can be expected of  $^{90}\text{Sr}$ ,  $^{137}\text{Cs}$ , and  $^{226}\text{Ra}$ .

A study of milk contamination is of particular interest, since strontium, cesium, and iodine enter into the human organism only with milk.

Contamination of cheese usually has its origin in the presence of  $^{89}\text{Sr}$  and/or  $^{90}\text{Sr}$  in milk. Contamination of meat can mostly be attributed to  $^{137}\text{Cs}$ . Contents of either  $^{131}\text{I}$  in the thyroid gland of animals or  $^{89}\text{Sr}$  and  $^{90}\text{Sr}$  in their bones may serve as indicators of the degree of environment contamination.

Water organisms (from plankton to fish) can concentrate certain radionuclides from their environment. Concentration effects were observed for the following elements: cobalt in mollusks; ruthenium in water plants; zinc, cadmium, and iron in fish bowels; calcium and strontium in bones and shells, etc.

Table 1 indicates the important radionuclides in evaluating contamination of the environment in the case of release from a nuclear facility and Table 2 lists those radionuclides in samples of human origin.

A somewhat different presentation of important nuclides is given in Table 3.

## Sampling, Sample Preservation, and Sample Pretreatment

In many cases, direct measurement cannot be made on environmental samples. Very often they must be

**Table 1** Samples for evaluating environmental contamination

Samples	Radionuclides
Air	All radionuclides dispersed with air
Water	All radionuclides dispersed with water
Soil	$^{90}\text{Sr}$ , $^{226}\text{Ra}$ , $^{137}\text{Cs}$
Plants	$^{131}\text{I}$ , $^{89}\text{Sr}$ , $^{90}\text{Sr}$ , $^{137}\text{Cs}$ , $^{226}\text{Ra}$ , $^{140}\text{Ba}$
Milk	$^{89}\text{Sr}$ , $^{90}\text{Sr}$ , $^{137}\text{Cs}$ , $^{131}\text{I}$ , $^{140}\text{Ba}$ , $^{226}\text{Ra}$
Milk products	$^{89}\text{Sr}$ , $^{90}\text{Sr}$ , $^{137}\text{Cs}$ , $^{226}\text{Ra}$
Meat	$^{137}\text{Cs}$
Thyroid gland	$^{131}\text{I}$
Bones	$^{89}\text{Sr}$ , $^{90}\text{Sr}$ , $^{226}\text{Ra}$
Water organisms	$^{89}\text{Sr}$ , $^{90}\text{Sr}$ , $^{137}\text{Cs}$ , $^{226}\text{Ra}$ , $^{141}\text{Ce}$ , $^{144}\text{Ce}$

preserved and analytes must be separated, concentrated, or sometimes transferred into another phase. Generally, therefore, a number of steps may be required prior to final measurements.

Standard and reference materials are exceedingly important for the verification of each step of the total procedure and calibration of the final measurement technique. Careful attention must be given to their preparation and use.

Special consideration must be given to sampling for the monitoring of radionuclides in the vicinity of nuclear facilities (all phases of the nuclear fuel cycle, radionuclide production, accelerator, medical and research facilities), or in the event of accidents involving the release of radioactive materials during shipment or storage (e.g., spills during shipment). In such cases, a surveillance program is needed to provide information used for dose calculations, comparison with regulatory standards, assessment of environmental contamination, countermeasures, and public information.

The objectives of such a program are as follows:

- assessment of actual or potential exposure to humans;

**Table 3** Relative importance of environmental media as a function of effluent pathway and radionuclide(s)

- evaluation of long-term trends in the environment;
- study of the fate of contaminants;
- baseline information and database maintenance;
- evaluation of offsite sources of radiation;
- compliance with regulations.

Factors that need to be considered include the following:

- potential hazards, including quantities and radio-toxicities;
- size and distribution of the exposed population;
- cost-effectiveness;
- availability of resources, including personnel, equipment, techniques, time, and money.

It must be possible to make adequate comparison with standards, reference materials, and background measurements.

The flow diagram given in **Figure 2** can be used as an aid in relating data requirements and critical path analysis to overall program planning.

In the case of nuclear facilities, both offsite and onsite sampling is required, in conjunction with pre-operational programs. A preoperational program should consist of:

- identification of critical exposure pathways;
- identification of population groups susceptible to exposure in the event of a release from the facility;
- selection of types of samples and sampling sites;

- accumulation of a background database;
- interpretation of information obtained.

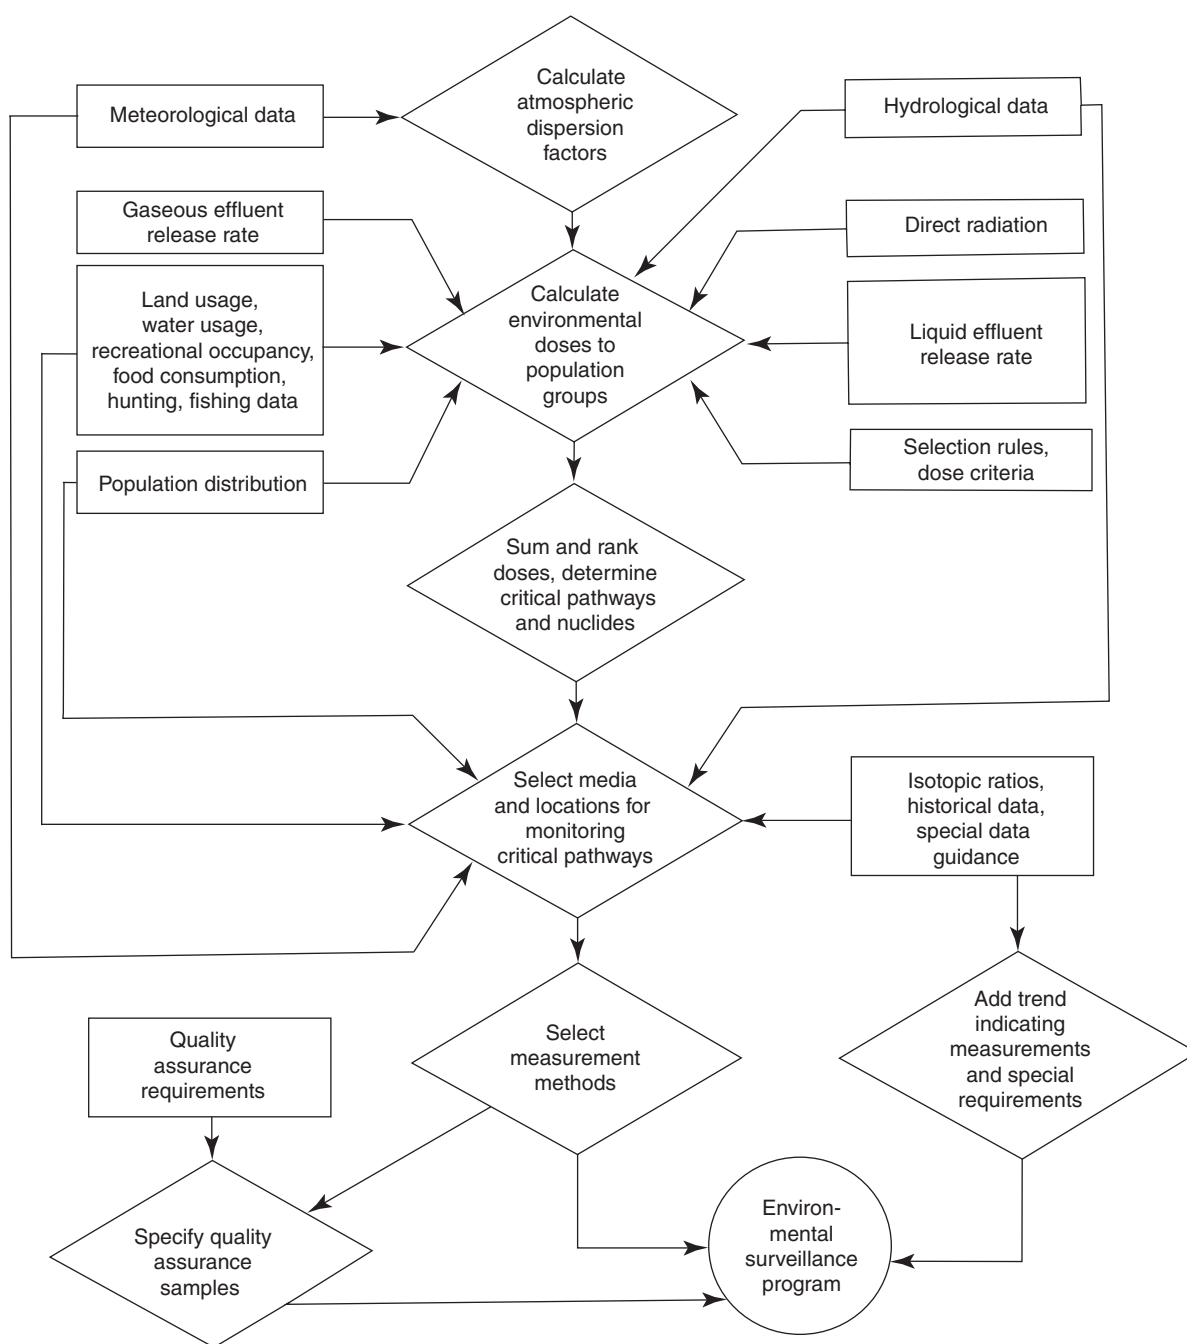

Once the facility is operational, continuous surveillance is needed to monitor effluents and the surrounding environment. Such programs rely heavily on the critical exposure pathway concept.

In general, sampling techniques for the monitoring of radionuclides in the event of a nuclear accident are based on standard procedures and are similar to those already discussed. It must be remembered that the sampling program is at least as important as the measurements made on the samples, and this is especially true for nuclear accidents.

### Analysis of Natural Radioactive Elements

Natural radioactive elements can be determined by measuring the activity of appropriate radioisotopes.

**Radon and radium** In nature, radon is most often associated with uranium deposits, since some of its isotopes are formed as part of the natural decay series. In isolated samples, radon will reach radioequilibrium in about 3 h, and the total rate of  $\alpha$  particle emission will be three times that for radon itself. This is because for each  $\alpha$  particle from radon decay, approximately one from <sup>218</sup>Po and one from <sup>214</sup>Po will also be emitted. Since the half-life of <sup>210</sup>Po (22 years) is long compared to analysis times, its decay can be neglected. However, since analysis times are still

**Figure 2** Environmental surveillance program design process. (Reproduced from CRC Press, Inc., Baco Raton, FL.)

significantly long, the decay of the radon itself must be taken into account.

The determination of radium by the emanation method is based on the production of radon as a decay product of radium. From a liquid sample, the radon is first flushed out with a carrier gas. The end of the flushing is taken as the starting time for fresh radon accumulation in the sample. After a suitable time, the radon reaches equilibrium in the sample

and is then transferred to the counting device by a second flushing with a carrier gas (e.g., 15%  $\text{H}_2 + 85\% \text{N}_2$ ). After the radon isotopes have reached radioequilibrium with their daughters in the detector (3–4 h), a measurement is made. The measured radon activity is used to calculate the amount of radium in the sample. The method can detect as little as  $10^{-2}$  g of radium. Ionization chambers and  $\alpha$ -scintillation cells coupled to a

photomultiplier can be used for measurement of activity.

**Actinium** The nuclide  $^{219}\text{Rn}$  can be used for the determination of actinium:

The  $^{219}\text{Rn}$  activity of a sample is compared to that of a standard with a known content of  $^{223}\text{Ra}$ , which is prepared from a uranium ore containing a negligible amount of thorium. In such cases, it can be assumed that the ratio of  $^{235}\text{U}/^{238}\text{U}$  is 0.007. Since the decay products are short-lived, equilibrium is attained within a few minutes. Amounts of actinium as small as  $10^{-14}\text{ g}$  have been determined by this method.

**Thorium** The only gaseous product in the thorium decay series is thoron, which has a very short half-life (56 s). It can be used to determine  $^{220}\text{Rn}$ , and also its parent,  $^{232}\text{Th}$ . Thorium is determined by comparison with a standard, but because of the short half-life of  $^{220}\text{Rn}$ , decay correction must be made. Naturally occurring thorium cannot be used as a standard because of the presence of  $^{230}\text{Th}$ . If the sample is not in equilibrium, corrections must be made for the presence of long-lived isotopes such as  $^{228}\text{Ra}$  and  $^{228}\text{Th}$ . The  $^{220}\text{Rn}$  activity must be measured dynamically in the stream of carrier gas. A solution of known thorium content (1–10 mg) is used as a standard.

**Measurement of  $^{222}\text{Rn}$  and  $^{220}\text{Rn}$  in mixtures** The determination of  $^{222}\text{Rn}$  and  $^{220}\text{Rn}$  in mixtures is relatively simple because of the difference in half-life values (3.8 days and 56 s). One technique consists of measuring the combined activity of the nuclides as a function of time. The total activity first decreases by decay of  $^{220}\text{Rn}$ . After reaching a minimum value, it rises moderately with time because of the growth of daughter products of  $^{222}\text{Rn}$ . The ratio of the active components may be determined from an activity versus time curve.

**Protactinium** The significant isotope is  $^{231}\text{Pa}$ , a member of the  $^{235}\text{U}$  decay chain. Its radiometric determination is based on the measurement of  $\alpha$  activity, after a chemical separation of the element using a scintillation or semiconductor counter.

**Uranium** Determination of uranium by measuring its activity is of considerable practical significance in searching for uranium deposits, in its technical processing, and also when monitoring the environment. Direct methods, based on measurement of  $\alpha$ -particles

or photons emitted by uranium isotopes and indirect methods, based on measurement of other members of the decay chain, are used. The direct measurement of uranium in macroamounts is possible by use of the 0.184 MeV  $\gamma$ -ray of  $^{235}\text{U}$ . This technique also serves to determine the enrichment of uranium with  $^{235}\text{U}$ . Indirect methods are frequently used for uranium determination, even though difficulties can arise from the possible lack of equilibrium with decay products. It is therefore important to use methods that do not require equilibrium conditions, or to know the degree of equilibrium. Prospecting for uranium deposits with a GM or scintillation counter represents a field application of the indirect determination of uranium. Equilibrium is usually assumed, and the results are expressed as 'uranium equivalent' after comparison with a  $\text{U}_3\text{O}_8$  standard.

## Monitoring of Mixtures of Radionuclides

Monitoring of mixtures of radionuclides can include:

- identification of the number and nature of the radionuclides present in the mixture;
- determination of the relative radioactivity of each, e.g., the ratio of the count rates of one radionuclide in two complex mixtures of different composition;
- quantitative measurements, i.e., the determination of the quantity of each radionuclide (in becquerels).

The first of these tasks can be approached by considering the method of producing the mixture, the chemical behavior of the radioactive species compared to that of various inactive carriers, the half-life values, the type and energy of the radiation emitted, and the branching ratios of the radiation.

The second task is the one most frequently met in monitoring work. It can be solved in many different ways, but basically there are two typical approaches: (1) To add inactive carrier in known amounts, allow for isotope exchange, separate, and purify until further purification does not influence the characteristics of the radiation, and measure the radioactivity and chemical yield; the measurement of radioactivity in this case need not be discriminatory. (2) Without chemical pretreatment, to measure the intensity at one energy only (if no other radionuclides emitting at the same energy are present) or to use the difference in half-lives to differentiate between two (or more) radionuclides, as shown in Figure 3.

The third task, quantitative measurement, is equivalent to the determination of the number of

**Figure 3** Decay of  $^{214}\text{At}$  and  $^{212}\text{Po}$   $\alpha$  peak 8.78 MeV, 10 min irradiation of Th. Half-life of  $^{212}\text{Po}$  = 60.6 min, of  $^{214}\text{At}$  =  $1.28 \pm 0.19$  min. (Reproduced from Tölgyessy J and Kyrš M (1989) Radioanalytical Chemistry, vols. I and II. Chichester: Ellis Horwood.)

disintegrations of a given radionuclide per second (Bq). Absolute quantitative calibration here includes the determination of individual efficiency factors, which can be expressed as percentages and multiplied together to give the overall efficiency.

#### $\alpha$ -, $\beta$ -, and $\gamma$ -Spectrometry

In  $\gamma$ -ray spectrometry, a mixture of  $\gamma$ -ray emitting radionuclides can be resolved quantitatively by pulse-height analysis. The analysis is based on the fact that the pulse heights (in volts) produced by a phototube are proportional to the amounts of  $\gamma$ -ray energy arriving at the scintillation detector. The amplification of the pulse is proportional to the voltage applied to the phototube, which can be adjusted so that the entire  $\gamma$ -spectrum can be examined.

In a single-channel counting procedure, only pulses of a certain height are counted; pulses of smaller or larger height are not registered ('seen') by the pulse-height analyzer. These pulse-height 'windows' are set by two pulse-height selectors.

In multichannel analysis the pulses are sorted according to height by a digital computer, and after a certain period of measurement, the distribution of the number of pulses according to height is obtained.

The number of counts registered in a certain channel (energy interval), plotted against channel number, is called a  $\gamma$  (or  $\alpha$ , or  $\beta$ ) spectrum. The  $\gamma$ -radiation of a simple radionuclide having a unique  $\gamma$ -energy does not produce a sharp spectral line, but a peak, owing to the statistical nature of the interaction of  $\gamma$ -rays with matter.

An NaI(Tl) scintillation detector spectrum for  $^{137}\text{Cs}$  is shown in **Figure 4**. The peak at channel No. 100 is due to backscatter and corresponds to 0.184 MeV; the edge at channel No. 180 is the Compton edge with energy 0.478 MeV, and the peak at

**Figure 4** NaI(Tl) spectrum of  $^{137}\text{Cs}$ . (Reproduced from Tölgyessy J and Kyrš M (1989) Radioanalytical Chemistry, vols. I and II. Chichester: Ellis Horwood.)

channel No. 280 is the photopeak (0.662 MeV), which is characteristic for  $^{137}\text{Cs}$ . The average width of the photopeak is 32 channels. The resolution (in per cent) characterizing the discriminating power of a detector is defined as  $100\delta E/E$ , where  $\delta E$  is the average width (full width of the peak at half of the maximum (FWHM) count level) of a photopeak, and  $E$  is its energy. For the purpose of finding the resolution of a detector (relative to a certain energy or source) the energy can be expressed in channel numbers. Therefore, in this case resolution with respect to  $^{137}\text{Cs}$  is  $100\delta E/E = 3200/280 = 11.5\%$ .

An energy calibration for a detector consists of finding the linear dependence between particle energy (MeV) and channel number.

It is evident that analyses of mixtures of radionuclides are not simple, for the multiplicity of types of interaction of  $\gamma$ -rays with the detector material generally leads to complicated  $\gamma$ -ray spectra. Besides the peak due to total absorption (photopeak at  $E$ ) peaks are caused by the following: pair production and escape of one or both annihilation photons ( $E$  0.51 or 1.02 MeV),  $180^\circ$  Compton scattering, single Compton scattering, multiple Compton scattering, external Compton scattering, and iodine K X-rays (from the NaI(Tl) crystal). For analysis and measurement of spectra of mixed  $\gamma$ -radiation, it is convenient and precise to measure only the contribution to the spectra resulting from total energy absorption.

If a semiconductor (such as hyper-pure germanium) is used instead of an NaI(Tl) scintillation detector, the resolution is improved by a factor of 30 and more. The tremendous increase in resolution compared to scintillation detectors is shown in **Figure 5**. Here, a spectrum is shown of lead bullet

**Figure 5**  $\gamma$ -Spectrum of an irradiated lead bullet. (Reproduced from Tölgyessy J and Kyrš M (1989) *Radioanalytical Chemistry*, vols. I and II. Chichester: Ellis Horwood.)

containing  $\sim 0.8\%$  Sb and 350 mg per kg As, which has been irradiated for 2 min at  $\sim 10^{12}$  neutrons  $\text{cm}^{-2}\text{s}$ . Peak 1 corresponds to 0.511 MeV (channel 226) from annihilation radiation, peak 2 to 0.559 MeV (channel 226) from  $^{122}\text{Sb}$ ; peak 4 to 0.603 MeV (channel 320) from  $^{124}\text{Sb}$ . The upper curve is an expanded portion of a spectrum taken with a  $3 \times 3$  in. NaI(Tl) crystal, with a resolution of 7% for 0.622 MeV. The lower curve is the spectrum of the same energy range taken with a Ge(Li)

low-energy photon detector, with an integral cooled preamplifier. On the other hand, the efficiency of Ge(Li) detectors is only 10–30% of that of a  $3 \times 3$  in. NaI(Tl) detector. The efficiency of one of the largest Ge(Li) detectors ever manufactured is 50% of the value that would be obtained from the standard  $3 \times 3$  in. NaI(Tl) detector.

The advent of high-resolution semiconductor  $\gamma$ -ray spectrometers opened a new era in the acquisition of accurate analytical data, which otherwise could not be obtained without great effort spent on chemical separation.

On the other hand, the interpretation of these spectra remains rather complicated, and analysis of the spectra is done by computer techniques. The major problem is the occurrence of interferences. Each peak used for quantitative analysis may have its own characteristic problems. The analysis begins with the integration of the counts in each peak of interest, and subtraction of the background counts, which are obtained from regions of the spectrum adjacent to the peaks.

$\beta$ -ray spectrometry, as a means of identifying and measuring mixtures of  $\beta$ -emitting nuclides by  $\beta$ -energy resolution, is very difficult because of the continuous energy spectra of  $\beta$ -radiation. On the other hand, monoenergetic conversion electrons yield spectra that can be relatively easily interpreted, and it is even possible to discriminate the peaks corresponding to the different binding energies of the electrons.

For  $\alpha$ -spectrometry, silicon charged-particle detectors (surface-barrier detectors) have been used. They can be used over an extensive range of energies (20 kV–200 MeV). The inherent resolution of these surface-barrier detectors is surpassed only by that of magnetic spectrometers.

Their resolution in a spectrum is calculated as  $\delta(\Delta E/\Delta C)$ , where  $\Delta E/\Delta C$  is the slope of the linear region of the calibration graph for  $\alpha$ -spectrometry (i.e., the slope of a plot of energy  $E$  (MeV) against channel number  $C$ ) and  $\delta$  is again the FWHM of the peak (in channel numbers). The resolution is then given in keV. In a typical  $^{210}\text{Po}$   $\alpha$ -spectrum, the energy peak at 5.305 MeV occurs in channels 512–528 with its maximum in channel 520; the resolution is  $(5.305/520) \times 8 = 0.082$  MeV.

Another advantage of these detectors is the fact that the detector output pulses rise rapidly, and hence they are well suited for fast ( $\sim 1$  ns) timing with coincidence circuitry in time-to-pulse-height converters. The efficiency of the active volume of these detectors is essentially 100%, and  $\Delta E/\Delta C$  is linear over a rather broad range. Compared to scintillation counters, gas proportional counters or ionization

**Figure 6**  $\alpha$ -Spectrum of spallation products after 1 min irradiation of Th with 600 MeV protons: 1 –  $^{226}\text{Th}$ ; 2 –  $^{226}\text{Th}/^{221}\text{Fr}$ ; 3 –  $^{222}\text{Ra}/^{223}\text{At}$ ; 4 –  $^{223}\text{Ac}/^{221}\text{Bi}$ ; 5 –  $^{222m}\text{Ac}/^{225}\text{Th}/^{221}\text{Ra}$ ; 6 –  $^{218}\text{Ra}$ ; 7 –  $^{219}\text{Fr}$ ; 8 –  $^{214}\text{Po}$ ; 9 –  $^{217}\text{Ra}$ ; 10 –  $^{218}\text{Fr}$ ; 11 –  $^{215}\text{At}$ ; 12 –  $^{213}\text{Po}$ ; 13 –  $^{214}\text{At}/^{212}\text{Po}$ . (Reproduced from Tölgyessy J and Kyrš M (1989) *Radioanalytical Chemistry*, vols. I and II. Chichester: Ellis Horwood.)

chambers, they also have good long-term pulse-height stability. Moreover, they are relatively inexpensive.

A typical detector may exhibit a resolution of 16 keV for  $^{241}\text{Am}$   $\alpha$  particles, have an active area of 50 mm<sup>2</sup>, and a depletion depth of 100  $\mu\text{m}$ .

An example of a complicated  $\alpha$  spectrum is given in Figure 6.

Prior chemical separation is used to simplify the subsequent determination based on physical principles. On the other hand, the introduction of this chemical operation renders the overall determination more complicated. Therefore, a decision to include chemical separation should be made carefully.

Prior separation can be either complete (i.e., individual substances are separated) or partial (with enrichment of some components in certain fractions). The latter is more frequently used when sophisticated measuring equipment is available. In many cases, prior chemical separation is done after the addition of isotopic carriers.

The main task in the monitoring of radionuclides in fission products (nuclides produced by primary and secondary processes associated with fission, generally of the uranium isotopes  $^{235}\text{U}$  and  $^{238}\text{U}$ ), transuranium nuclides, and transplutonium elements is the identification of nuclides and the determination of yield. A

combination of instrumental and chemical technique is required and the work is laborious and difficult.

## Technetium

**B Salbu**, Agricultural University of Norway, Ås, Norway  
**E Holm**, Lund University, Lund, Sweden

## Origin and Nature

The discovery of technetium is attributed to Perrier and Segre, who, in 1937, identified the element after

**Figure 6**  $\alpha$ -Spectrum of spallation products after 1 min irradiation of Th with 600 MeV protons: 1 –  $^{226}\text{Th}$ ; 2 –  $^{226}\text{Th}/^{221}\text{Fr}$ ; 3 –  $^{222}\text{Ra}/^{223}\text{At}$ ; 4 –  $^{223}\text{Ac}/^{221}\text{Bi}$ ; 5 –  $^{222m}\text{Ac}/^{225}\text{Th}/^{221}\text{Ra}$ ; 6 –  $^{218}\text{Ra}$ ; 7 –  $^{219}\text{Fr}$ ; 8 –  $^{214}\text{Po}$ ; 9 –  $^{217}\text{Ra}$ ; 10 –  $^{218}\text{Fr}$ ; 11 –  $^{215}\text{At}$ ; 12 –  $^{213}\text{Po}$ ; 13 –  $^{214}\text{At}/^{212}\text{Po}$ . (Reproduced from Tölgyessy J and Kyrš M (1989) *Radioanalytical Chemistry*, vols. I and II. Chichester: Ellis Horwood.)

chambers, they also have good long-term pulse-height stability. Moreover, they are relatively inexpensive.

A typical detector may exhibit a resolution of 16 keV for  $^{241}\text{Am}$   $\alpha$  particles, have an active area of 50 mm<sup>2</sup>, and a depletion depth of 100  $\mu\text{m}$ .

An example of a complicated  $\alpha$  spectrum is given in Figure 6.

Prior chemical separation is used to simplify the subsequent determination based on physical principles. On the other hand, the introduction of this chemical operation renders the overall determination more complicated. Therefore, a decision to include chemical separation should be made carefully.

Prior separation can be either complete (i.e., individual substances are separated) or partial (with enrichment of some components in certain fractions). The latter is more frequently used when sophisticated measuring equipment is available. In many cases, prior chemical separation is done after the addition of isotopic carriers.

The main task in the monitoring of radionuclides in fission products (nuclides produced by primary and secondary processes associated with fission, generally of the uranium isotopes  $^{235}\text{U}$  and  $^{238}\text{U}$ ), transuranium nuclides, and transplutonium elements is the identification of nuclides and the determination of yield. A

combination of instrumental and chemical technique is required and the work is laborious and difficult.

## Technetium

**B Salbu**, Agricultural University of Norway, Ås, Norway  
**E Holm**, Lund University, Lund, Sweden

## Origin and Nature

The discovery of technetium is attributed to Perrier and Segre, who, in 1937, identified the element after

chemical isolation of products obtained from irradiation of molybdenum with deuterons. However, other claims to its discovery were made earlier, in 1908 by Ogawa, who named the element nipponium, and in 1925 by Noddack, Tacke, and Berg, who named it masurium.

The element, with atomic number 43 in the periodic table, was named technetium, a word derived from Greek meaning artificial. Thus, the name reflects the artificial origin of being produced by nuclear reactions, as no stable isotope of the element exists. Twenty-one radioactive isotopes of technetium and seven isomers are known from nuclear chemistry. Of these, only three isotopes have long physical half-lives:  $^{97}\text{Tc}$  ( $T_{1/2} = 2.6 \times 10^6$  years),  $^{98}\text{Tc}$  ( $T_{1/2} = 4.2 \times 10^6$  years), and  $^{99}\text{Tc}$  ( $T_{1/2} = 2.1 \times 10^5$  years). Being a long-lived fission product from neutron-induced fission of  $^{235}\text{U}$  and  $^{239}\text{Pu}$ ,  $^{99}\text{Tc}$  is the only technetium isotope of any radiological significance in the environment.

The major sources contributing to  $^{99}\text{Tc}$  in the environment are fallout from atmospheric nuclear weapons tests and releases from the nuclear fuel cycle, i.e., authorized or accidental releases from nuclear installations (e.g., reprocessing or enrichment plants, nuclear reactors), releases from waste disposal sites, and from dumping of nuclear materials. Contributions from natural processes, i.e., spontaneous fission of  $^{238}\text{U}$  in mineral ores such as pitchblende or nuclear reactions in molybdenum ores irradiated with cosmic-ray neutrons are negligible.

Technetium has been transferred to terrestrial and aquatic ecosystems due to the fallout from atmospheric nuclear weapons tests. It is assumed that 1 Mt fission energy corresponds to  $1.45 \times 10^{26}$  fissions and that  $^{137}\text{Cs}$  is produced with a representative fission yield of 5.57%. Assuming that the global stratospheric injection of nuclear debris was  $\sim 168.5$  Mt and a fission yield of  $^{99}\text{Tc}$  of  $\sim 6\%$ , similar to that of  $^{137}\text{Cs}$ , the global activity of  $^{99}\text{Tc}$  released into the stratosphere is 160 TBq. When local fallout is included, the total release of  $^{99}\text{Tc}$  into the environment from nuclear weapons tests between 1945 and 1963 should be within 180–200 TBq. Any releases from underground nuclear weapon tests are assumed to have a local impact only.

Releases from the nuclear fuel cycle may occur during reactor operations, nuclear fuel reprocessing,  $\text{UF}_6$  conversion, uranium enrichment, uranium fuel fabrication, high-level waste solidification, high-level and low-level waste disposals. The enrichment process, with a significant annual release through liquid discharges to the sea, is considered as the key contributor. So far, the total release of  $^{99}\text{Tc}$  to the

environment from the nuclear fuel cycle, e.g., reprocessing plants, is estimated to be  $\sim 1500$  TBq.

Reprocessing plants situated in coastal areas represent a major source of  $^{99}\text{Tc}$  to the marine environment. The Sellafield reprocessing plant on the Irish Sea has allowed the authorized release of  $\sim 770$  TBq to the marine system during 1952–94, with a maximum annual release of 178 TBq in 1978. Since 1994, the discharges from Sellafield into the Irish Sea increased significantly, due to processing of backlog liquid waste stored at the site since 1980s. The release of  $^{99}\text{Tc}$  in 1995 (190 TBq) was probably the highest annual release in the plant's history. In 2000, the permitted annual technetium discharges were reduced from 200 to 90 TBq, due to high activity concentrations in biota from the Irish Sea. Thus, during 1994–2001, additional 600 TBq was released to the marine environment. The release of  $^{99}\text{Tc}$  from the reprocessing plant Cap de la Hague, France, was estimated to be  $\sim 130$  TBq during 1976–2001. Information on authorized and accidental releases of  $^{99}\text{Tc}$  to terrestrial ecosystems or to freshwater drainage systems from large reprocessing facilities in the former USSR, e.g., Chelyabinsk (Mayak PA), Krasnoyarsk (KMCIC), or Tomsk (SCC) is not available. However, significant amount of  $^{99}\text{Tc}$  have been identified in ground water and artificial reservoirs associated with Techa River in the close vicinity of the Mayak PA.

Releases from nuclear power plants during normal operations are small, as  $\sim 1$  MBq (25% to the atmosphere) is released annually from a 1000 MW(e) boiling water reactor or pressurized water reactor. With a total capacity of 369 000 MW(e) in 1990 and an operational experience of 6000 reactor years with a mean capacity of 700 MW(e), the annual and integrated release of  $^{99}\text{Tc}$  corresponds to 350 MBq and 4 GBq, respectively. Uncontrolled releases during accidents are, however, more difficult to assess and are usually estimated from radionuclide ratios. In the fallout from the Chernobyl accident the radionuclide ratio  $^{99}\text{Tc}/^{137}\text{Cs}$  was reported to be  $1.5 \times 10^{-5}$ , i.e., significantly lower than the theoretical estimate for fission,  $1.43 \times 10^{-4}$ . Based on estimated total release of  $^{137}\text{Cs}$  and the reported radionuclide ratio, the total release of  $^{99}\text{Tc}$  from Chernobyl amounts to  $\sim 0.75$  TBq.

Information on releases of  $^{99}\text{Tc}$  from waste disposal sites or from dumping of wastes including reactors with fuel in the marine environment, e.g., Kara Sea including bays of Novaya Zemlya, is not available.

Radiopharmaceuticals containing  $^{99}\text{Tc}$  produced from molybdenum–technetium generators represent an additional source of  $^{99}\text{Tc}$  to the environment. The

isotope ratio  $^{99}\text{Tc}/^{99\text{m}}\text{Tc}$  in a  $^{99}\text{Mo}$  generator used for medical purposes is  $\sim 0.1\text{--}2 \times 10^{-7}$  depending on the elution pattern. All the  $^{99}\text{TcO}_4^-$  produced from  $^{99}\text{Mo}$  generators will eventually reach the environment. With an annual discharge of  $\sim 200\text{ kBq}$  from an ordinary medical department, nuclear medicine will only contribute to minor releases of  $^{99}\text{Tc}$ .

## Chemical and Physical Properties

Technetium-99 is produced by fission, e.g.,

The products are neutron-rich  $\beta$ -emitters, and the precursors of  $^{99}\text{Tc}$  are the refractory elements zirconium, niobium, and molybdenum:

During release and initially after deposition of fission products, fractionation between volatile elements associated with condensed particles ( $^{137}\text{Cs}$ ,  $^{90}\text{Sr}$ ) and refractory elements associated with fuel particles ( $^{99}\text{Zr}$ ,  $^{99}\text{Nb}$ ) may take place. The behavior of  $^{99}\text{Tc}$  in the environment will, therefore, depend on whether technetium is released as such or formed from precursors after deposition. Technetium-99 is believed to be released from the nuclear fuel cycle as the volatile heptaoxide ( $\text{Tc}_2\text{O}_7$ ) in air emissions or as soluble and highly mobile pertechnetate ( $\text{TcO}_4^-$ ) in effluents.

Knowledge of the complex chemistry of technetium is primarily based on laboratory experiments using the isotopic tracers  $^{99\text{m}}\text{Tc}$  ( $T_{1/2} = 6.02\text{ h}$ ),  $^{97}\text{Tc}$  ( $T_{1/2} = 2.6 \times 10^6\text{ years}$ ),  $^{97\text{m}}\text{Tc}$  ( $T_{1/2} = 90\text{ days}$ ), and  $^{95\text{m}}\text{Tc}$  ( $T_{1/2} = 61\text{ days}$ ). In aqueous solution, the physicochemical forms of technetium will depend on pH and redox conditions (Eh). From Eh–pH diagrams it can be deduced that  $\text{TcO}_4^-$  is the only stable physicochemical form in aerobic natural waters. Under anaerobic conditions, however,  $\text{TcO}_4^-$  is reduced to  $\text{TcO}_2$ ,  $\text{TcO}(\text{OH})_2$ , or  $\text{TcCl}_6^{2-}$ . Technetium-species in oxidation state IV may associate with organic material such as humic substances in anoxic sediments, and thereby behave as organic colloids.

For  $^{99}\text{Tc}$ , the low-level energy  $\beta$ -particles emitted ( $E_{\text{max}} = 292\text{ keV}$ ) and the low concentrations in environmental samples represented an analytical challenge prior to the late 1970s. Based on a radiochemical procedure developed in 1969, the activity concentrations of  $^{99}\text{Tc}$  in waters ranged from  $0.019$  to  $1.8\text{ Bq l}^{-1}$ , and the detection limit was reached for 80% of the samples ( $n = 150$ ). For rainwater samples collected in 1967, the activity concentrations

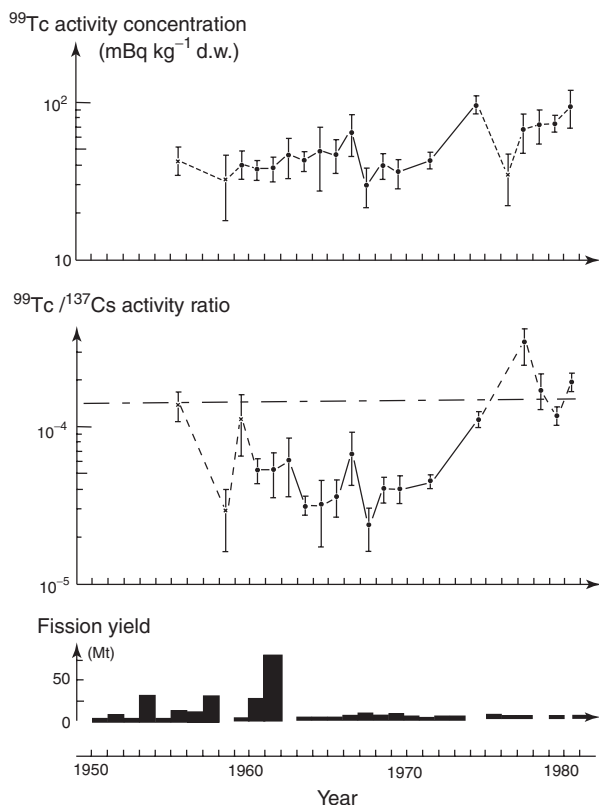

ranged from  $5.2 \times 10^{-5}$  to  $6.3 \times 10^{-4}\text{ Bq l}^{-1}$ , while  $7.5 \times 10^{-5}\text{ Bq l}^{-1}$  was reported for  $^{99}\text{Tc}$  in composite rain samples collected in 1975. Thus, analytical considerations should be taken when these results are compared with recent measurements.

During recent years, research has demonstrated that  $^{99}\text{Tc}$  behaves conservatively in natural water systems. Fractionation of discharge waters from the reprocessing plant in Sellafield showed that the colloidal fraction was significant for plutonium isotopes and refractory elements, while  $^{99}\text{Tc}$  was present as low molecular mass species, presumably  $^{99}\text{TcO}_4^-$ . Technetium-99 is therefore considered highly mobile and its retention in sediments and soils is most often negligible, especially when compared to transuranics. Since the 1980s,  $^{99}\text{Tc}$  and  $^{137}\text{Cs}$  released from European reprocessing facilities have successfully been used to trace water currents and identify water masses over temperate and Arctic waters of the North Atlantic. Analyses of  $^{99}\text{Tc}$  in groundwater from Nevada test sites also indicate the presence of mobile forms in solution, while  $^{99}\text{Tc}$  associated with colloids has been observed in ground water from Mayak. However, in reducing environments such as anoxic sediments,  $\text{Tc(VII)}$  can be reduced to  $\text{Tc(IV)}$ . Technetium in oxidation state IV can be retained in sediments or may associate with humic substances forming organic colloids. The relatively high retention of  $^{99}\text{Tc}$  in reservoir sediments at Mayak has also been attributed to the reduction of  $\text{Tc(VII)}$  in an anoxic environment.

## Common Matrices in Which the Element is Found

Deposition of  $^{99}\text{Tc}$  in terrestrial ecosystems is globally attributed to atmospheric fallout, while releases from installations associated with the nuclear fuel cycle may have a local or regional impact.

The deposition of  $^{99}\text{Tc}$  from weapon fallout has been estimated to be  $540 \pm 50\text{ mBq m}^{-2}$  at  $62^\circ\text{N}$ . Frequently, carpets of mosses and lichens are used as bioindicators for the estimation of deposited radionuclides. The concentration of  $^{99}\text{Tc}$  in lichens (mBq per kg dry weight), the fission yields (Mt) for nuclear weapons testing, and the observed and theoretical  $^{99}\text{Tc}/^{137}\text{Cs}$  radionuclide ratios are given in **Figure 1**. The present  $^{99}\text{Tc}/^{137}\text{Cs}$  ratio is expected to be  $3.2 \times 10^{-4}$  due to the physical decay of  $^{137}\text{Cs}$ . In general, the observed  $^{99}\text{Tc}/^{137}\text{Cs}$  ratio is lower than expected from fission probably due to a shorter residence time for  $^{99}\text{Tc}$  in the lichen carpet. The concentration of  $^{99}\text{Tc}$  and the  $^{99}\text{Tc}/^{137}\text{Cs}$  ratio in lichens has increased since 1975. Unusual mixtures of short-lived radioisotopes, e.g.,  $^{239}\text{Np}$  and  $^{99}\text{Mo}$ , in fallout

**Figure 1** Concentration of  $^{99}\text{Tc}$  (mBq kg<sup>-1</sup> dry weight) and  $^{99}\text{Tc}/^{137}\text{Cs}$  ratio in lichen. Individual results are marked with an x. The  $^{99}\text{Tc}/^{137}\text{Cs}$  ratio expected from fission is marked with a dotted line. In the lower part of the figure fission yields of atmospheric nuclear weapon tests are shown. (Reproduced with permission from Holm E and Riosco J (1987)  $^{99}\text{Tc}$  in the sub-arctic foodchain lichen-reindeer-man. *Journal of Environmental Radioactivity* 5: 343; © Elsevier.)

have also been reported on several occasions during 1975 and 1976, at a time when depositions from preceding nuclear tests were at their lowest.

Based on measurements of air filters from 1965 to 1967 and rainwater samples from 1967, the  $^{99}\text{Tc}/^{137}\text{Cs}$  ratio seems to be a factor of 10 higher than expected from the fission yield. The anomalous ratios of fission products observed in the atmosphere may partly be explained by fractionation of radionuclides during the detonation process. The precursors of  $^{137}\text{Cs}$  are gaseous or volatile elements, i.e., xenon and iodine, while the precursors of  $^{99}\text{Tc}$  are refractory elements, i.e., zirconium and niobium, which are usually incorporated in radioactive particles. Thus, the  $^{99}\text{Tc}/^{137}\text{Cs}$  ratio in the atmosphere may decrease with time after detonation due to the deposition of large radioactive particles. For deposited material releases of  $^{99}\text{Tc}$  with time should be expected due to weathering of particles. However, we cannot, at this stage, exclude additional sources contributing to releases of  $^{99}\text{Tc}$  to the atmosphere.

Such sources have not, however, significantly altered the integrated deposition.

Due to discharges from European reprocessing plants, radionuclide contamination of surface waters and marine biota are observed in the Irish Sea, North Sea, Norwegian Sea, Barents Sea, Kara Sea, North Atlantic, and the Polar Sea. The activity concentration in surface waters and biota such as *Fucus vesiculosus* decreases with distance to the source, e.g., reprocessing plants, or reflects global fallout. Using available data for  $^{90}\text{Sr}$ , which similar to technetium behaves conservatively in the water column, and known radionuclide ratios from fission, the concentration of  $^{99}\text{Tc}$  in surface waters is expected to be  $\sim 1 \text{ mBq m}^{-3}$ . However, from measurements of the bioindicator *F. vesiculosus*, having a concentration factor *F. vesiculosus* (dry weight)/water of  $\sim 10^5$ , the concentration in the surface waters should be  $\sim 10 \text{ mBq m}^{-3}$ . As seen in Table 1 enhanced values for  $^{99}\text{Tc}$  and for the  $^{99}\text{Tc}/^{137}\text{Cs}$  ratio are observed in areas exposed to releases from European reprocessing facilities. Radionuclide ratios in the range of 0.0018–0.049 are significantly much higher than those expected from fission.

Due to discharges from Mayak PA in the Urals, Russia, during 1949–51 into River Techa and during 1951 until present into Lake Karachay, groundwater, river water, and sediments (artificial reservoirs) were contaminated by a series of radionuclides, including  $^{99}\text{Tc}$ . In 1994, activity concentrations of  $^{99}\text{Tc}$  up to  $10 \text{ Bq l}^{-1}$  were observed in groundwater, reflecting vertical transport from the Lake Karachay. About 10–15% of  $^{99}\text{Tc}$  was associated with colloids, pseudocolloids, and particles. In 1996, the highest concentrations in river waters were observed in Reservoir 4, close to Mayak;  $\sim 2000 \text{ Bq l}^{-1}$  of  $^{137}\text{Cs}$ ,  $10 \text{ Bq l}^{-1}$  of  $^{99}\text{Tc}$ , and a  $^{99}\text{Tc}/^{137}\text{Cs}$  ratio of 0.005. The retention of  $^{99}\text{Tc}$  in sediments was relatively high ( $K_d \sim 10^4$ ) in the reservoirs and oxidizing reagents were needed for its extraction. Thus,  $^{99}\text{Tc}$  in the sediments was not present as pertechnetate, but was probably reduced and associated to organic sediment components. When sediments were exposed to artificial seawater, a few per cent of  $^{99}\text{Tc}$  could be remobilized. Thus,  $^{99}\text{Tc}$  could be released to the marine environment if contaminated sediments are transported by rivers to estuaries during flooding.

In areas contaminated mainly from global fallout, such as the Mediterranean, Davis Strait, and to some extent the Baltic proper before the Chernobyl accident, the concentrations and radionuclide ratios in surface waters are, however, also a factor of 5–20 higher than what should be expected from fission yields. This can partly be explained by the decay of

**Table 1** Activity concentrations of  $^{99}\text{Tc}$  and activity ratios to  $^{137}\text{Cs}$  in surface waters from different areas<sup>a</sup>

Year of collection	Sample area	$^{99}\text{Tc}$ ( $\text{mBq l}^{-1}$ )	$^{99}\text{Tc}/^{137}\text{Cs}$ activity ratio ( $\times 10^3$ )
1969	Irish Sea	$4.5 \pm 0.9$	8
1972	Irish Sea	$108 \pm 7$	36
1995	W. Irish Sea	$21 \pm 6$	—
1995	E. Irish Sea	100–500	1000–1600
1980	North Sea	$0.7 \pm 0.1$	—
1981	North Sea	$3.5 \pm 0.4$	20
1985–86	Mediterranean	$0.07 \pm 0.03$	20
1986–87	Mediterranean	$0.03 \pm 0.01$	0.8
1983	Baltic Sea	$0.07 \pm 0.01$	5
1986	Baltic Sea	$0.04 \pm 0.01$	0.2
1980	Norwegian Sea	$0.36 \pm 0.13$	7
1999	Norwegian Sea	$0.97 \pm 0.08$	17
1980	Barents Sea	$0.56 \pm 0.23$	7
1999	Barents Sea	0.3–1.1	—
1984	Davis Strait	$0.04 \pm 0.02$	11
1988	Greenland Sea	$0.08 \pm 0.01$	—
1999	Danish Straits	0.1–2	1–600
1994	Japan Sea	0.001–0.007	27
2001	Swedish W. Coast	$1.05 \pm 0.17$	18–85

<sup>a</sup>References: Brown JE, Iospje M, Kolstad KE, *et al.* (2002). $^{137}\text{Cs}$  and from a possible shorter residence time of  $^{137}\text{Cs}$  in the water column. The  $^{99}\text{Tc}/^{90}\text{Sr}$  ratio is also much higher than expected from fallout and the results are in agreement with more recent observations for atmospheric sample. We cannot, however, exclude systematically analytical errors in the earlier studies of  $^{99}\text{Tc}$  in seawater. After 1986, following the Chernobyl accident, a much lower  $^{99}\text{Tc}/^{137}\text{Cs}$  ratio is observed in contaminated areas since relatively small amounts of  $^{99}\text{Tc}$  were released. On the other hand, after 1994, much higher ratios ( $^{99}\text{Tc}/^{137}\text{Cs}$ ,  $^{99}\text{Tc}/^{90}\text{Sr}$ ) are found in areas contaminated from the discharges from Sellafield, due to the significant increase of  $^{99}\text{Tc}$  in effluents from that year.

To study the long-distance marine transport of  $^{99}\text{Tc}$  from European reprocessing facilities, samples of *Fucus* were collected in temperate and arctic regions of the North Atlantic and the Baltic Sea. **Figure 2** shows the activity concentration of  $^{99}\text{Tc}$  in *F. vesiculosus* ( $\text{Bq kg}^{-1}$  dry weight) as a function of distance from the Sellafield reprocessing plant. The

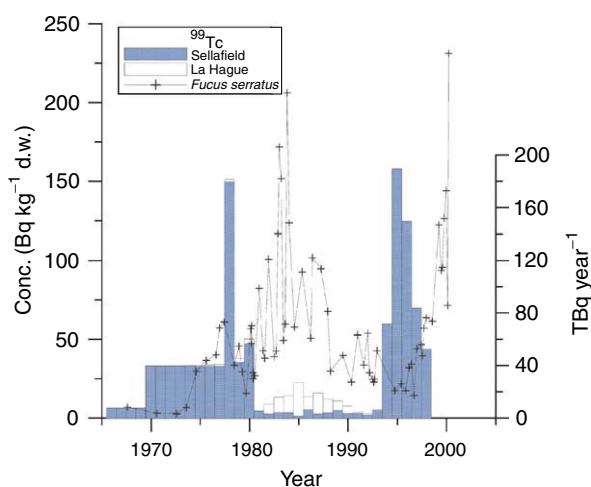

**Figure 2** Concentrations of  $^{99}\text{Tc}$  ( $\text{Bq kg}^{-1}$  dry weight) in *Fucus vesiculosus* from different areas as a function of transport distance (km) from European reprocessing facilities. The transit time (years) is indicated. (Reproduced with permission from Holm E and Rioseco J (1987).  $^{99}\text{Tc}$  in the subarctic foodchain lichen-reindeer-man. *Journal of Environmental Radioactivity* 5: 343; © Elsevier.)

estimated transit times to different regions is also indicated in the figure. The results show that  $^{99}\text{Tc}$  enters the North Sea and is effectively guided along the Norwegian coast by the Gulf current. The concentration decreases only by a factor of about three along the Norwegian coast (a distance of 2000 km), while the decrease along the Swedish coast into the Baltic Sea is more rapid due to the large yearly net outflow of water into the North Sea. The  $^{99}\text{Tc}$  activity concentrations in *F. serratus* at a site at the Swedish west coast (Särdal,  $56.76^\circ\text{N}$ ,  $12.63^\circ\text{E}$ ) collected from 1967 to 2001, with the annual releases from Sellafield and La Hague, are presented in **Figure 3**. The transit time of Sellafield-derived  $^{99}\text{Tc}$  to this site is shown to be 4–5 years. Utilizing the 1994/95  $^{99}\text{Tc}$  pulse from Sellafield, the transit time of  $^{99}\text{Tc}$  to the North Channel, North Sea, and Barents Sea seems to be more rapid than expected from previous estimates.

## Sampling, Handling, and Storage of Samples

The amount or volume of environmental samples needed for analysis for  $^{99}\text{Tc}$  depends on the degree of contamination (i.e., distance to the source) and the sensitivity of the measurement technique (i.e., detection limits). In the Irish Sea water, volumes of 10–50 L may be sufficient, while 50–100 l is needed in the Arctic Seas. For areas contaminated only from weapon fallout, volumes up to 1000 l may be needed. Especially in coastal areas or in high production areas filtration of waters through  $0.45 \mu\text{m}$  membrane is recommended, as algal materials, in particular,

**Figure 3** Technetium-99 activity concentration in *Fucus serratus* (primary axis) from Särda (56.76° N, 12.63° E), 1967–2000, and annual  $^{99}\text{Tc}$  activity discharge (secondary axis) from Sellafield (UK) and La Hague (France).

should be removed prior to the analysis. An effective method is to sorb technetium in the filtrate on activated carbon resins. Furthermore, the application of preconcentration techniques onboard the ship, e.g., anion-exchange chromatography or co-precipitation, are advantageous, as no storage effects will influence the analytical results. Also, the volumes transferred to laboratories are significantly reduced. Otherwise, waters should be stored cold (4°C) and in darkness in order to reduce algal or bacterial growth.

In freshwaters, *in situ* filtration and ultrafiltration techniques are useful to distinguish  $^{99}\text{Tc}$  associated with colloidal material such as humic substances.

In areas close to reprocessing plants the amount of marine bioindicators needed, i.e., *Fucus*, is ~1 g (dry weight), while in fallout areas 20–50 g (dry weight) should be sufficient. For lichens and mosses in fallout areas up to 200 g (dry weight) materials are usually needed. The bioindicators are most often air-dried prior to incineration and homogenization.

## Methods of Determination at Trace Levels

Even though neutron activation methods have been described for the determination of 0.1 pg amounts of technetium in environmental samples, radiochemical techniques have been most extensively used since the 1980s. In 1984, a general radioanalytical method was developed for the determination of  $^{99}\text{Tc}$  in environmental samples by radiochemical separation and low-level Geiger–Müller counting. A method suitable for large volumes of water was described in 1988. More sensitive analytical techniques using

mass spectrometry have been developed during the 1990s.

Determination of  $^{99}\text{Tc}$  in environmental samples represents an analytical challenge, as the low concentrations involved require the separation of a low-level  $\beta$ -emitter. The concentrations of  $^{137}\text{Cs}$  and  $^{210}\text{Pb}$  are frequently  $10^4$ – $10^6$  times higher than the concentrations of  $^{99}\text{Tc}$  and interferences from other major  $\beta$ -emitter contaminants such as  $^{103}\text{Ru}$ ,  $^{106}\text{Ru}$ , and  $^{110}\text{Ag}$  must be controlled. The separation of  $^{99}\text{Tc}$  is generally performed by anion-exchange chromatography followed by liquid–liquid extraction of technetium into cyclohexanone, extraction into 5% triisooctylamine, or extraction of  $^{99}\text{Tc}$  from a sulfuric acid solution into tributyl phosphate. Co-precipitation techniques in combination with anion-exchange chromatography have also been successfully applied.

When radiochemical separations are performed, the chemical yields reflecting possible losses must be determined. Among the tracers used (i.e.,  $^{99\text{m}}\text{Tc}$ ,  $^{97}\text{Tc}$ ,  $^{97\text{m}}\text{Tc}$ ,  $^{95\text{m}}\text{Tc}$ , and stable Re), the most suitable yield monitors, especially for preconcentration of large water volumes in the field, are  $^{99\text{m}}\text{Tc}$  and stable Re. When the short-lived  $^{99\text{m}}\text{Tc}$  obtained from  $^{99}\text{Mo}$  ( $T_{1/2} = 66.7$  h) is used, the Mo–Tc generator and a detector system must be brought in the field to perform yield determinations. When the stable chemical analog rhenium is used, the final source is a precipitate of the Re(Tc) tetraphenylarsonium salt,  $(\text{C}_6\text{H}_5)_4\text{AsReO}_4$ , and the recovery is obtained by gravimetric determination. When  $^{97\text{m}}\text{Tc}$  is used as a yield monitor, the quantities needed can frequently cause significant interference in the  $\beta$ -measurements. Although  $^{95\text{m}}\text{Tc}$  is more useful as a yield determinant than  $^{97\text{m}}\text{Tc}$ , it is not easily commercially available. The long-lived  $^{97}\text{Tc}$  is, however, useful in analysis of  $^{99}\text{Tc}$  using mass spectrometry techniques.

At very low levels of  $^{99}\text{Tc}$  in environmental samples and in the presence of much higher concentrations of interfering radionuclides, proper quality control may be a problem as  $\beta$ -spectrometry by solid-state detectors or liquid scintillation cannot be applied. So far, to our knowledge, two international analytical quality control exercises have been performed: one by the International Atomic Energy Agency, Monaco, using seaweed contaminated from a reprocessing plant and one performed by Environmental Measurement Laboratory, New York, using a grass sample contaminated from a gaseous diffusion plant. Both exercises were successful, but did not cover today's need for low-level intercalibration of  $^{99}\text{Tc}$  in environmental samples.

The recent development of mass spectrometry techniques such as inductively coupled plasma-mass

spectrometry (ICP-MS), high-resolution ICP-MS, accelerator mass spectrometry (AMS) improves the detection limits significantly (Table 2). For ICP-MS, the large range in the detection limits given reflects different instrument performances, depending on several factors such as systems (e.g., quadrupole) and type of sample introduction systems (e.g., nebulizers or ETV). Using time-of-flight instruments and AMS the detection limits can be lowered to the  $\mu\text{Bq}$  (fg) region. However, radiochemical separation is still needed prior to measurements and interferences from other nuclides, e.g.,  $^{99}\text{Ru}$  and  $^{99}\text{Mo}$ , should be removed or depressed. For analysis of  $^{99}\text{Tc}$  using ICP-MS and AMS, radiochemical separation based on ion chromatography (TEVA resins) and  $^{99\text{m}}\text{Tc}$  as yield monitor has proved successful.

## Areas of Special Interest and Safety Considerations

Radioecological interest in  $^{99}\text{Tc}$  started in the mid-1970s. In 1973, high concentration levels of  $^{99}\text{Tc}$

were reported in the seaweed *F. vesiculosus* as a result of effluents released from the nuclear fuel reprocessing plant on the Irish Sea coast. During the 1980s,  $^{99}\text{Tc}$  was successfully used together with  $^{137}\text{Cs}$  as a tracer to map water currents and to identify water masses over temperate and Arctic waters of the North Atlantic using known releases from European reprocessing facilities. As the disposal of high-level radioactive wastes in geological media could also result in releases, the potential migration of technetium in geological formations has also been discussed.

Information on biological uptake and accumulation of  $^{99}\text{Tc}$  in organisms is generally scarce, but has improved following the increased Sellafield discharges from 1994. In 1997, the  $^{99}\text{Tc}$  concentrations in crustacea, particularly in lobster, increased relatively rapidly, peaking at  $16\,000\text{ Bq kg}^{-1}$ , a factor of 10 higher than the European Council Food Intervention Level (CFIL) for  $^{99}\text{Tc}$  ( $1250\text{ Bq kg}^{-1}$  for adults) for postaccident situations. In 1998, the activity concentrations of  $^{99}\text{Tc}$  in *F. Vesiculosus* increased in the coastal area of Cumbria (up to  $200\,000\text{ Bq kg}^{-1}$ ), in the coastal areas of West Scotland (up to  $30\,000\text{ Bq kg}^{-1}$ ), in the coastal areas of Ireland (up to  $5000\text{ Bq kg}^{-1}$ ), and the North Sea ( $500\text{ Bq kg}^{-1}$ ) and the Norwegian Sea. As illustrated for *Laminaria hyperborea* (Figure 4), the accumulation of  $^{99}\text{Tc}$  in stipes exceeds that of the blades. The continuing accumulation of  $^{99}\text{Tc}$  in the algal stipes indicates that the peak effect of the discharges in *L. hyperborea* may not yet have occurred.

**Table 2** Limits of detection for the determination of  $^{99}\text{Tc}$

Analytical method	Detection limit (mBq)
Anti-coincidence shielded gas flow counting	1–5
Neutron activation ( $n, \gamma$ )	3–5
Liquid scintillation counting	1–25
ICP-MS	0.01–15
AMS	0.005–0.010

<sup>a</sup>Dry weight basis for algae.

For  $^{99}\text{Tc}$ , probably present as pertechnetate, the concentration factor (CF) varies according to biological species (Table 3). The CF is high for seaweed ( $\sim 10^5$ ) and low for fish fillet ( $\sim 10$ ). For lobster (tail muscle) recent results showed that the CF is  $\sim 10^3$ , which is a factor of 10 higher than previously measured in laboratory experiments. For edible parts of mussels and oysters, the CF is about 500 and 300, respectively. After the ingestion of contaminated lobster from the Irish Sea, 4–7% of  $^{99}\text{Tc}$  was retained in the body 1 year after intake. Thus, there seems to be a long-term compartment in the body retaining  $^{99}\text{Tc}$  and the dose conversion factor should be revised.

The possible uptake of technetium by plants and the risk of technetium transfer through the animal food-chain increased the environmental importance of this radionuclide. When studying  $^{99}\text{Tc}$  in carpets of lichen, the transfer to reindeer and to a limited degree to wolves and cattle was investigated. Figure 5 shows that the activity concentrations in liver and kidney of 2-year-old reindeer were significantly higher than those in their flesh.

A simple compartment model has been used to describe the transfer of technetium through the food-chain lichen-reindeer, as the uptake from food is much more important than from inhalation. The mean residence time for bone, liver, and flesh was 55, 11, and 5 days, respectively, giving a dose to the liver of  $0.02 \mu\text{Gy year}^{-1}$ , to the bone  $0.06 \mu\text{Gy year}^{-1}$ ,

**Figure 5** Activity concentrations of  $^{99}\text{Tc}$  ( $\text{mBq kg}^{-1}$  dry weight) in various reindeer tissues, wolves, and cattle during the period 1963–81. (Reproduced with permission from Holm E, Rioseco J, Ballestra S, and Walton A (1988) Radiochemical measurements of  $^{99}\text{Tc}$ : Sources and environmental levels. *Journal of Radioanalytical Nuclear Chemistry* 123: 167; © Elsevier.)

and to the flesh  $0.006 \mu\text{Gy year}^{-1}$ . Based on a literature survey, a  $^{99}\text{Tc}$  soil-to-plant concentration ratio of 50 ( $\text{Bq kg}^{-1}$  fresh weight tissue per  $\text{Bq kg}^{-1}$  dry weight soil) was applied, instead of the currently used value of 0.25, to evaluate the dose in man from a  $37 \text{GBq a}^{-1}$  release to the atmosphere from a hypothetical uranium enrichment facility. Later these dose evaluations were revised and maximum doses to the gastrointestinal tract and thyroid were estimated at 8 and  $13 \mu\text{Sv}$ , respectively, in an adult living 1600 m from the facility.

It should be emphasized that there are still sources and accumulating ecosystem compartments to be identified and our understanding of the biogeochemical behavior of technetium in the environment, especially in freshwater systems, is rather limited. Furthermore, information on the transfer to humans and the behavior of technetium in the human body is needed for assessing the long-term consequences of its release to the environment. However, major progress within the field of radioecology and dosimetry of technetium is expected in the years to come due to the development of highly sensitive analytical techniques such as high-resolution ICP-MS and AMS.

## Radon

**L Tommasino**, National Agency for Environmental Protection and Technical Services, Rome, Italy

## Introduction

Radon ( $^{222}\text{Rn}$ ) is the dominant source of human exposure to ionizing radiation in every country of the world. It is dominant in most circumstances: at home and at work, for individual persons and for whole populations. The worst characteristic of radon, apart from its carcinogenicity, is its ubiquity. Before radon became a matter of concern for human exposure, it was studied and measured for many purposes. It was an inert tracer for air masses, it was a geological indicator for radium and uranium, and it was a short-lived source of  $\gamma$ -radiation for cancer treatment. Radon plus beryllium was used as neutron source by Fermi for the discovery of neutron-induced fission reactions.

It would be difficult to design a radionuclide with characteristics more suitable for easy separation and determination than  $^{222}\text{Rn}$ . A noble gas with no stable compounds, it can be readily separated from the myriad of solid radionuclides and the other radon isotopes disappear rapidly by decay.

The radon can be absorbed on charcoal at room temperature or condensed at dry ice temperature.

Another useful radon characteristic is the decay to both short-lived and long-lived solid radionuclides. These can either be left with the radon to augment its radioactivity or separated on an air filter or electrostatic collector for separate measurement.

## Origin and Nature

Radon is a radioactive noble gas, discovered during the early studies of radioactivity at the turn of the century. The term radon was first introduced by Schmit in 1918 to designate the element with atomic mass 222 ( $^{222}\text{Rn}$ ), i.e., the gas associated with uranium-238 ( $^{238}\text{U}$ ). In precise usage, the term radon has come to denote the element with atomic number 86. This element has 26 isotopes ranging from  $^{199}\text{Rn}$  to  $^{226}\text{Rn}$ , three of which are naturally occurring. These are  $^{219}\text{Rn}$  (initially called actinon) from the  $^{235}\text{U}$  decay series discovered by Debierne and Giesel in 1903,  $^{220}\text{Rn}$  (thoron) from the thorium decay series discovered by Owens and Rutherford in 1889, and  $^{222}\text{Rn}$  (radon) from the  $^{238}\text{U}$  series discovered by Dorn in 1901. In the following the term radon will refer to  $^{222}\text{Rn}$  unless otherwise stated. It was William Ramsay who first separated radon and determined the quantity of radon in equilibrium with 1 g of radium. This quantity became the original definition of the radioactivity unit called the curie. Moreover,

## Introduction

Radon ( $^{222}\text{Rn}$ ) is the dominant source of human exposure to ionizing radiation in every country of the world. It is dominant in most circumstances: at home and at work, for individual persons and for whole populations. The worst characteristic of radon, apart from its carcinogenicity, is its ubiquity. Before radon became a matter of concern for human exposure, it was studied and measured for many purposes. It was an inert tracer for air masses, it was a geological indicator for radium and uranium, and it was a short-lived source of  $\gamma$ -radiation for cancer treatment. Radon plus beryllium was used as neutron source by Fermi for the discovery of neutron-induced fission reactions.

It would be difficult to design a radionuclide with characteristics more suitable for easy separation and determination than  $^{222}\text{Rn}$ . A noble gas with no stable compounds, it can be readily separated from the myriad of solid radionuclides and the other radon isotopes disappear rapidly by decay.

The radon can be absorbed on charcoal at room temperature or condensed at dry ice temperature.

Another useful radon characteristic is the decay to both short-lived and long-lived solid radionuclides. These can either be left with the radon to augment its radioactivity or separated on an air filter or electrostatic collector for separate measurement.

## Origin and Nature

Radon is a radioactive noble gas, discovered during the early studies of radioactivity at the turn of the century. The term radon was first introduced by Schmit in 1918 to designate the element with atomic mass 222 ( $^{222}\text{Rn}$ ), i.e., the gas associated with uranium-238 ( $^{238}\text{U}$ ). In precise usage, the term radon has come to denote the element with atomic number 86. This element has 26 isotopes ranging from  $^{199}\text{Rn}$  to  $^{226}\text{Rn}$ , three of which are naturally occurring. These are  $^{219}\text{Rn}$  (initially called actinon) from the  $^{235}\text{U}$  decay series discovered by Debierne and Giesel in 1903,  $^{220}\text{Rn}$  (thoron) from the thorium decay series discovered by Owens and Rutherford in 1889, and  $^{222}\text{Rn}$  (radon) from the  $^{238}\text{U}$  series discovered by Dorn in 1901. In the following the term radon will refer to  $^{222}\text{Rn}$  unless otherwise stated. It was William Ramsay who first separated radon and determined the quantity of radon in equilibrium with 1 g of radium. This quantity became the original definition of the radioactivity unit called the curie. Moreover,

Ramsay was among the first to study the biological effects of the radioactive gas radon.

## Chemical and Physical Properties

Chemically, radon is a noble gas. As such, it is colorless, odorless, and almost chemically inert. Although radon is not chemically active, it is interesting to note that radon is not a totally 'inert' gas either. Studies on radon chemistry have been reported in which compounds such as clathrates and complex fluorides have been formed. Compared with the other noble gases, radon is the heaviest and has the highest melting point, boiling point, critical temperature, and critical pressure.

Some physical properties of radon are listed in Table 1. Radon is moderately soluble in water and, therefore, can be absorbed by water flowing through rock and sand containing radon. Its solubility depends on water temperature; the colder the water, the greater is radon's solubility. A measure of gas solubility in water is given by the solubility coefficient, which is defined as the ratio of the radon concentration in water to that in air. At 20°C, the solubility coefficient is  $\sim 0.25$ , which means that radon is distributed preferentially in air rather than in water (in

the ratio of 4:1 at 20°C). Another important property of radon is the fact that it is most soluble in organic liquids and it is readily absorbed on charcoal and silica gel. In a multiphase system at normal environmental temperature, radon concentrations are greatest, intermediate, and least in the organic liquid, gas, and the water phases, respectively. If the temperature is increased, the concentration in the gas phase increases at the expense of that in the liquid phase. These properties are successfully exploited for the determination of radon gas and for its extraction from other gases and/or liquids. For example, radon in water can be easily measured after its extraction by bubbling air through the water or by extracting radon from the water with organic liquid scintillators. Radon gas can be effectively removed from a sample of air by passing it through activated charcoal cooled to the temperature of solid carbon dioxide ( $-78.5^\circ\text{C}$ ). Radon desorption can be achieved by heating the charcoal to  $350^\circ\text{C}$ .

## Relative Abundance of the Radon Isotopes

The amounts of radon isotopes in the environment depend primarily upon the concentrations of  $^{238}\text{U}$ ,  $^{235}\text{U}$ , and  $^{232}\text{Th}$  (thorium-232) in the soil and rocks. Although these isotopes are radioactive, their half-lives are so long that the time since the formation of universe (i.e., the time since these radionuclides were formed) is not sufficient for them to have decayed to stable elements. In particular, the half-life of  $^{238}\text{U}$  is nearly equal to the estimated age of the earth. Only half of the earth's original endowment of uranium has decayed away. The abundance of  $^{232}\text{Th}$  in the earth's crust is somewhat higher than that of  $^{238}\text{U}$ , but because of the longer half-life of  $^{232}\text{Th}$  (see Table 2), the average rate of production of  $^{220}\text{Rn}$  in the ground is about the same as that of  $^{222}\text{Rn}$ .

Within the natural uranium isotopes, the relative abundance by weight is 99.28% for  $^{238}\text{U}$  and 0.72% for  $^{235}\text{U}$ . Hence,  $^{238}\text{U}$  predominates over  $^{235}\text{U}$  in the environment. These abundance ratios are necessarily the same for all the uranium isotopes on the earth, on all the planets, on meteorites, etc. A number of people have expressed surprise at the discovery of radon

**Table 1** Physical properties of  $^{222}\text{Rn}$

Property	Value
Atomic number	86
Boiling point at normal temperature and pressure	$-61.8^\circ\text{C}$
Density at normal temperature and pressure	$9.96\text{ kg m}^{-3}$
Coefficient of solubility at atmospheric pressure in water at the temperature of:	
0°C	0.57
20°C	0.250
37°C	0.167
100°C	0.106
Coefficient of solubility at atmospheric pressure and 18°C in:	
Hexane	16.56
Olive oil	29.00
Petroleum (liquid paraffin)	9.20
Toluene	13.24

Condensed data derived from NCRP (1988) *Measurements of Radon and Radon Daughters in Air*. National Council on Radiation Protection and Measurements, Report no. 97.

**Table 2** Properties of some members of the natural radioactive series

Series	Long-lived parent		Crustal abundance			Noble gas member	
	Isotope	Half-life (years)	$\mu\text{g kg}^{-1}$	$\text{Bq kg}^{-1}$	$\text{pCi g}^{-1}$	Isotope	Half-life
Uranium	$^{238}\text{U}$	$4.5 \times 10^9$	2.7	33	0.89	$^{222}\text{Rn}$	3.82 days
Thorium	$^{232}\text{Th}$	$14.1 \times 10^9$	8.5	34	0.92	$^{220}\text{Rn}$	55.6 s
Actinium	$^{235}\text{U}$	$0.7 \times 10^9$	0.02	1.5	0.04	$^{219}\text{Rn}$	3.96 s

on the moon. The real surprise should have been if no radon had been found, since such a finding would certainly require some new theories on the origin of the moon.

The slow decay of  $^{235}\text{U}$ ,  $^{238}\text{U}$ , and  $^{232}\text{Th}$  occurs through a long and complicated series of radioactive elements until they finally become stable lead isotopes. Most of the intermediate nuclides are isotopes of metals and are chemically reactive. Thus, they tend to stay within the material in which the uranium or thorium atom was originally deposited. The only exception is radon, which being a noble gas, does not interact chemically with other elements, and is free to move by diffusion and convection.

Of the three naturally occurring radon isotopes, only  $^{222}\text{Rn}$  has a sufficiently long half-life (3.825 days) to allow for release from the soil and rocks, where it was generated. This half-life is short enough to restrict transport by pure diffusion to short distances only, but once the radon has left the solid material and has become mixed with air, convection transport over longer distances (several meters) from the soil into both outdoor air and indoor environments is possible. In contrast, substantially less  $^{220}\text{Rn}$  reaches the atmosphere because its short half-life (55.6 s) limits the distance it can travel before decay. As for  $^{219}\text{Rn}$  (formed in the decay chain of  $^{235}\text{U}$ ), it

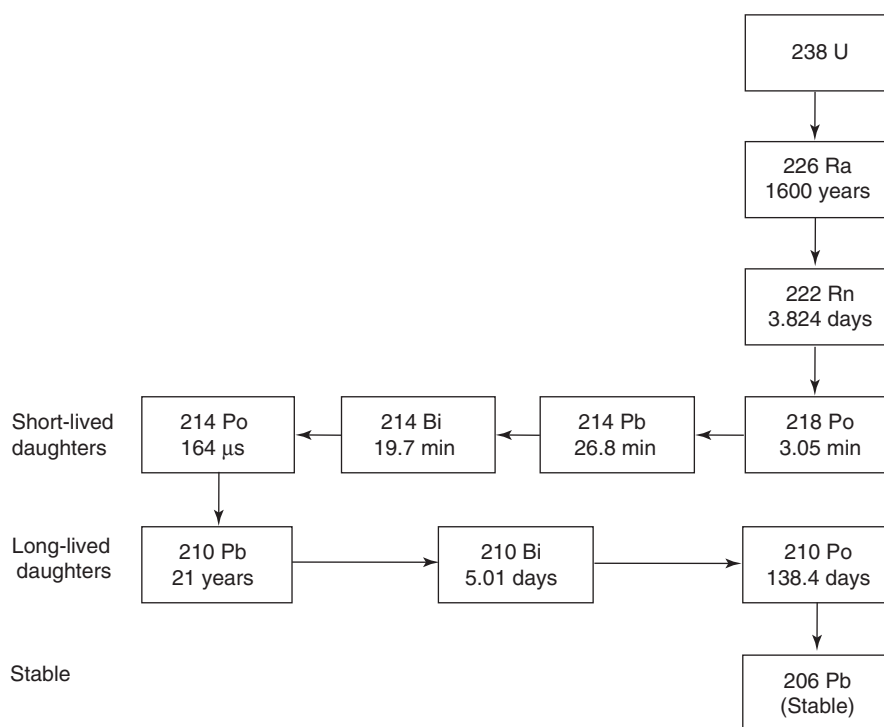

may be ignored entirely because of its short half-life (3.96 s) and the comparative scarcity of  $^{235}\text{U}$ .

## $^{222}\text{Rn}$ and its Decay Products

$^{222}\text{Rn}$  is preceded in the  $^{238}\text{U}$  decay series by radium ( $^{226}\text{Ra}$ ), which has a half-life of 1600 years.  $^{226}\text{Ra}$  decays to stable lead ( $^{206}\text{Pb}$ ), producing a chain of radioactive isotopes of solid elements. The decay chain of  $^{238}\text{U}$  is shown in Figure 1.

While the major removal of radon gas from air is by radioactive decay, the chemically radioactive decay products (formerly called radon daughters) may additionally be removed by processes such as wash-out and plating-out on surfaces. In air inside buildings, these radioactive decay products can attach themselves to walls, floors, people, or airborne particles that are inhaled into the lungs. Unattached radon decay products can also be inhaled and, subsequently, can become deposited on the lung tissue. As a consequence, radon decay products are seldom in radioactive equilibrium with radon in the lower atmosphere (near the earth's surface) or indoors.

An important characteristic from the radiological point of view is the fact that the four immediate radon decay products have half-lives of less than

**Figure 1** Uranium decay series showing radon and its decay products. (Reproduced with permission from Khan HA (1993) Passive dosimetry of radon and its daughters using solid state nuclear track detectors (SSNTDS). *Radiation Protection Dosimetry* 46: 149–170.)

30 min (Figure 1). Once inhaled, these products can undergo decay before they are removed by lung clearance mechanisms. In particular, the  $\alpha$ -particles emitted on decay are characterized by high linear energy transfer radiation, i.e., radiation with high biological effectiveness. Because of their short range in tissue (40–70  $\mu\text{m}$ ),  $\alpha$ -particles are stopped by the skin, but when emitted from inhaled decay products they irradiate epithelial cells, particularly in the bronchial region. The potential effect of the dose imparted to the lungs is an increase in the risk of lung cancer, as first observed with uranium miners. Because of its ubiquity, radon is the dominant source of human exposure to ionizing radiations.

### Radon in the Ground (Soil, Rocks, and Water)

The precursors of radon, namely radium and ultimately uranium, are present in all types of rocks and soil. Their amounts vary with the specific site and geological material. Uranium has a tendency to concentrate; it concentrates in magmas that form granites and in shales formed from marine mud high in organic matter. Because of uranium's chemical affinity for phosphates, phosphatic rocks often contain greatly elevated levels of uranium. Whenever rock is heated in the presence of a fluid, uranium has a tendency to move with the fluid until conditions change, when it stops and becomes concentrated. The end result is a wide variability in uranium concentration, even within the same rock formation or the same rock type. The concentration of both uranium and radium in the earth's crust as a whole is generally different from that of the soil. This is because soil concentrations are affected by the extent of leaching, porosity, precipitation from groundwater, etc. The effectiveness of radium in supplying radon to the soil pores for transport to the atmosphere depends both on the total concentration of radium atoms and on the fraction of those atoms in the soil (or rocks), which are located on the soil particle surfaces, so that the newly formed radon atoms can escape into the pores and capillaries.

For efficient release of radon into the air spaces of soil, the radon atom must be formed within 20–70 nm of the mineral surface for most common minerals. This distance is the recoil range of a radon atom at the instant of its formation from the decay of radium. The processes by which radon atoms escape from a given material are referred to as radon emanation. The emanation power or the coefficient of emanation is defined as the ratio of the number of radon atoms that escape from the solid to the number of radon atoms formed by radioactive decay of radium in the solid. The emanation power varies from about 0.02 to 0.7, depending upon the mineral structure and the water content.

A correlation between the amount of radon in the soil gas (or water) and the levels of  $^{238}\text{U}$  and  $^{226}\text{Ra}$  only exists for two extremes: the radon concentration in the soil gas is likely to be very low or very high if the radium content of the source materials (rock or sediment) is very low or very high, respectively. Outside these two extremes other factors dominate in controlling radon concentrations, with those factors responsible for the radon transport processes being especially important. These factors include soil porosity and permeability, density, moisture, barometric pressure, temperature, thickness of the soil over bedrock, and, in some cases, the underlying bedrock.

The most soluble of the noble gases, radon can be transported considerable distances by carrier gases or liquids such as carbon dioxide and water. The fracturing and faulting of a rock can alter its radon potential in several ways. Fracturing and faulting can create extensive migration pathways for radon, thus increasing the radon flow. Furthermore, fractures and faults are sometimes associated with elevated uranium concentrations because uranium-bearing fluids deposit the uranium within fracture or fault zones. Fractures and fault zones can be successfully identified by monitoring the radon concentration in the soil and they may be associated with houses that have the most severe indoor radon problems. Granitic rocks rich in uranium, especially when permeable and fractured, create the highest in-water concentration. Water penetrates into the voids present in the rocks and soil and dissolves radon that emanates into these spaces. Since seismic crustal activity should, in principle, affect the radon in the soil and groundwater, radon monitoring in the soil and well water has been used to study the complex precursor phenomena of earthquakes. When measuring radon in soil, the effects of changing weather on radon concentration are likely to be greater near the surface. A compromise between reducing the effects of weather and the practicability of sampling under field conditions is achieved by sampling soil radon from a depth of 0.5–0.7 m.

### Radon in the Atmosphere

Radon enters the atmosphere principally by crossing the soil–air interface. The transfer rate of radon across the interface between a solid phase and the atmosphere is referred to as a radon flux or exhalation rate. In SI units it is measured in  $\text{Bq m}^{-2} \text{s}^{-1}$ . The radon flux gives a measure of the source strength and varies strongly from soil to soil. A global average of  $\sim 17 \text{ mBq m}^{-2} \text{s}^{-1}$  from continental soil has been estimated.

Secondary sources of radon include the oceans and fluids that leave the earth and subsequently come

**Table 3** Sources of global atmospheric radon

Source	Input to atmosphere (million Ci per year) <sup>a</sup>
Emanation from soil	2000
Ground water	500
Emanation from oceans	30
Phosphate residues	3
Uranium mill tailings	2
Coal residues	0.02
Natural gas	0.01
Coal combustion	0.001

<sup>a</sup> 1 Ci =  $3.7 \times 10^{10}$  Bq.

into contact with the atmosphere (such as groundwater, natural gases, geothermal fluids, volcanic gases). Overall, as a global average, ~80% of the radon emitted into the atmosphere comes from the top layers of ground. **Table 3** lists the major sources of global atmospheric radon. The concentration of the radon in the atmosphere is governed by the source strength and dilution factors, both of which are strongly affected by meteorological conditions, particularly temperature, humidity, atmospheric pressure, and wind conditions at the surface. As a consequence, radon concentration exhibits both daily and seasonal variations that are often cyclic. Because of its modest half-life and origin at the ground surface, atmospheric radon exhibits a vertical concentration profile, which normally ranges from a maximum at the air–soil interface to an immeasurably low value in stratosphere. In particular, radon concentrations may drop by a factor of 10 in the first kilometer. For this reason, it is necessary to specify the altitude when talking of outdoor radon concentrations.

Atmospheric radon concentrations at 1 m from the ground are lower than those in soil by a factor of ~1000. This sharp drop is due to fast mixing in the air and the relatively short half-life of  $^{222}\text{Rn}$ . Isotopes of radon gas and their decay products provide a unique set of tracers for the study of transport and mixing processes in a wide variety of atmospheric phenomena. The  $^{222}\text{Rn}$  isotope has been more widely used because of its longer half-life and the greater relative abundance in the free atmosphere. For near ground level, tracer studies have been based on thoron mainly because of its short half-life (55.6 s). Since the ocean represents a poor radon source compared with the soil and rocks of continental areas, marine air masses contain only 1% or less radon per unit volume than air over large land areas. Collection

of air samples at sea can be useful in identifying radon-rich air masses that have originated from land areas.

### Indoor Radon

Most of the sources of outdoor atmospheric radon, such as soil, water, and natural gas, are also sources of indoor radon. The amount of air available for radon dilution in a structure is less than that available outdoors. As a consequence, levels of indoor radon are typically much greater than those found outdoors. As soil and groundwater are the major radon sources, large radon concentrations may exist in mines, caves, underground workplaces, and thermal spas. In the case of dwellings, emphasis was first placed on building materials as source of radon. It was not until the 1980s that soil was identified as an important source, especially for single family houses and ground-level workplaces. Subsequent detailed US studies led Nero to attribute virtually all of the radon excess over the outdoor level to the soil contribution. However, these conclusions may well apply to US homes, where the building material is essentially made of wood, but not in those countries where the building material could be even the soil itself.

It is believed that the basic mechanism that brings soil gas into the house is the pressure difference between the indoor and the outdoor environments. This pressure-driven flow (movement from a high- to a low-pressure area) is enhanced in the winter by a 'stack effect', similar to that encountered in the chimney. This chimney effect is created by the continuing rising of heated air as shown in **Figure 2**. In addition to the stack effect, contributions to the house depressurization arise from wind effects, the use of appliances that consume indoor air, etc.

The main characteristic of indoor radon levels, however, is their variability. Besides soil factors, building characteristics such as airtightness, permeability of cellar floors, doors between floors, building materials, microclimate (temperature, wind), water supply, number of occupants, and living habits have all been shown to influence indoor radon concentrations. Different comprehensive surveys of radon in houses have been carried out in several countries. One of the most striking results is the observed large variation in the radon levels from house to house. The value of the radon concentration covers a range from a few up to several thousands of  $\text{Bq m}^{-3}$  and in a few extreme cases, values up to ~200 000  $\text{Bq m}^{-3}$  have been measured. Just close to the house with extremely large radon concentration, it was possible to find other houses with very low radon levels.

**Figure 2** Radon infiltration from the subsoil into the indoor environment driven by the temperature differences (stack effect). (Reproduced with permission from Burkart W (1989) Radiation biology of the lung. *The Science of the Total Environment* 89: 1–230.)

A realistic quantitative prediction of the radon levels in existing houses seems impossible and measurements are finally the only reliable method for the detection of houses with high radon levels. Large-scale surveys of indoor radon have been carried out for different purposes. They can be classified respectively as:

- ‘Screening’ surveys for the investigation of geographical variations of the indoor radon distribution and for the identification of houses with high radon concentrations.
- Statistically representative surveys for the evaluation of the population doses.

Large-scale surveys for the assessment of the population exposure require a multitude of different detectors to be deployed in the primary living spaces (namely bedrooms) for year-long integrated measurements in several thousands dwellings. The most suitable detectors for these large-scale surveys are track-etch detectors. In contrast, short-term measurements are appropriate for screening surveys.

## Health Effects

The available epidemiological data of studies of underground miners exposed to radon decay products provide a direct assessment of lung cancer

mortality. An important aspect of this approach is that the levels of exposure are not a great deal higher than those found in the home, even for average home exposure. The analogy between working age males laboring in mines with families sleeping in their bedrooms may not be perfect. However, even though the risks of exposure to radon and its decay products in dwellings are not well characterized, their potential lung cancer risks need to be strongly addressed, both in homes and occupational environments. The risk of dying from a lifetime exposure to average indoor radon concentration is estimated to be in the range of 0.1–1%, depending on country and smoking habits. These risks are in the same order of magnitude as risk of dying in a fall at home or a home fire. Moreover, houses having several times the average radon concentration have radon risks that can equal or exceed the 2% risk of death in an automobile accident. Since it is not possible to predict where these high values will be found, screening surveys are needed to identify the houses with high indoor radon concentrations.

These data alone do not solve the radon problem. It is important to know that efficient and low-cost techniques for the reduction of the radon inflow from the soil, like subpressurization, are now being developed and tested. At the present stage of knowledge, the most effective remediation approach seems to be that of reversing the driving force behind radon inflow. The International Commission of Radiological Protection has recommended an intervention level of  $400 \text{ Bq m}^{-3}$  for existing dwellings as the concentration above which remedial action should be considered. The most reasonable approach is to apply a step-wise system of action levels for the concentration of radon. According to this approach, the higher the observed concentration, the shorter should be the time period for remedial actions.

## Monitoring Radon and Its Decay Products

There is no radionuclide with characteristics more suitable for easy separation and determination than  $^{222}\text{Rn}$ . A noble gas with no stable compounds, it can be readily separated from the myriad of solid radionuclides and the other radon isotopes disappear rapidly from decay. The radon can be absorbed on charcoal at room temperature or condensed at dry ice temperature. Another useful radon characteristic is the decay to both short-lived and long-lived solid radionuclides. These can either be left with the radon to augment its radioactivity or separated on an air filter or electrostatic collector for separate measurement.

Techniques for measuring the concentration of radon and its decay products have been developed in two large fields of investigations: earth sciences and radioprotection. In spite of such different fields of application, radon monitoring deals with the investigation of similar processes. For example, high indoor radon concentrations are related to gas migration processes that derive from the geological formation, from the soil and from underground water. The same processes are of interest for geological risk prediction (earthquake, vulcanism), mineral prospection (uranium and oil), hydrogeology, geothermy, etc.

The characteristics of the measuring techniques will depend on whether the quantity to be measured is the concentration of radon (be it in air, in water, or in soil) or of the radon decay products. Both these measurements are based on the detection of radiation emitted from radioactive decay in combination with a suitable sampling technique. The whole spectrum of radiation detectors could be used, but most methods rely on detection of  $\alpha$ -particles; some are based on detection of  $\gamma$ -emissions and only a few utilize  $\beta$ -decays.

## Airborne Radon Monitoring

In the case of radon gas measurement, the major problem is the low sensitivity of existing instruments for accurate routine analysis at radon concentrations near the indoor average, which has a worldwide arithmetic mean of  $40 \text{ Bq m}^{-3}$ . At this concentration, in each liter of air, there will be  $\sim 2.2$  decays per minute of  $^{222}\text{Rn}$ . Even with further decays of the radon progenies, this implies low counting rates. Each  $\alpha$ -particle decay of  $^{222}\text{Rn}$  is shortly followed by the  $\alpha$ -particle decays of  $^{218}\text{Po}$  and  $^{214}\text{Po}$ . Thus, there will be about seven  $\alpha$ -particles per minute for each typical value of radon concentration of  $40 \text{ Bq m}^{-3}$ . If these were counted with 100% efficiency, with no contribution from extraneous counts, a counting period of  $\sim 1 \text{ h}$  would be needed to yield 400 events. From simple statistical considerations, this means that the radon concentration is determined to within  $\sim 10\%$ , if the background rates are low compared to the radon counting rates. For most measurements of outdoor levels and for many measurements indoor, the radon concentration is less than  $40 \text{ Bq m}^{-3}$ , background counts cannot be neglected, and the problems of low counting rates are still greater.

Sufficient accuracy for these low-level measurements can be achieved by increasing the volume of air sampled, or by lengthening the sampling or analysis time. In particular, the time duration of the

measurement determines three broad classes of sampling procedures:

- grab sampling method for the measurement of the content of radon of a sample of air at a single instant in time,
- continuous sampling method for the study of the time dependence of the radon concentration, and
- integrating sampling methods for short- and long-term measurements, i.e., determination of radon concentration averaged over a period of a few days to a year.

Another important classification is based on whether the sampling method and/or technique is passive or active. Active instrument technique is used by forced sampling of air by pumps. In passive systems, the sampling of radon is based on natural diffusion without any power supply.

The terms active and passive are also often used to designate radiation detectors that operate with and without power supply, respectively. To avoid confusion, this classification should be made simply by denoting detectors with or without real-time response. In particular, a radon monitor may be formed by any possible combination of active or passive sampling systems and real-time or no real-time detectors. In spite of the many possible combinations of detectors and sampling procedures, some guidelines may be drawn from the experiences accumulated to date. In particular, total passive monitoring systems work well for the measurement of radon gas alone, being the most suitable for large-scale survey of radon concentrations in indoor air. By contrast, the measurements of radon daughters can successfully be carried out by total active monitoring systems, i.e., by using active sampling and real-time  $\alpha$ -detection and spectrometry. This type of monitoring is particularly useful for extensive investigations in a limited number of dwellings. Some of the currently available radon gas monitoring devices are described in the following and listed in Table 4.

### Grab Sampling Method

This method involves filling a container with an air sample of radon and transferring it to a laboratory for analysis. One of the most useful devices is the scintillation flask, known as the Lucas cell. This consists of a chamber whose walls are coated with a scintillating material such as silver-activated zinc sulfide. The cell is optically coupled to a photomultiplier tube to count the light pulses (scintillation) induced by the  $\alpha$ -particles interacting with the zinc sulfide coating. The scintillation flask can be filled either by evacuation or by airflow using a

**Table 4** Currently available radon measurement devices

<i>Instrument</i>	<i>Sampling type</i>	<i>Sensitivity<sup>a</sup> (Bq m<sup>-3</sup>)</i>
Scintillation cell	Grab or continuous	0.37–37
Diffusion electrostatic collection on scintillator	Continuous	<3.7
Ionization chamber	Grab or continuous	0.5–37
Two-filter method	Grab or continuous	0.74–3700
Activated charcoal	Integrating	7.4 (for 100 h exposure)
Track detector	Integrating	3.7 (for 100 days exposure)

<sup>a</sup>Sensitivity is defined as the smallest quantity that can be distinguished from background with a 95% confidence level.

Derived from Corthen CR and Smith JE Jr (1987) *Environmental Radon*. Environmental Science Research, no. 35. New York: Plenum Press.

pump. For accurate measurements, a delay of at least 3 h is used prior to counting to allow the development of a radioactive equilibrium of polonium-214. The efficiency of these cells is typically 70–80%. The lower level of detection (LLD) depends on several parameters such as the size of the flask, counting intervals; typical values are  $\sim 37 \text{ Bq m}^{-3}$  ( $1 \text{ pCi l}^{-1}$ ) or less.

### Continuous Sampling

For continuous sampling, there is no single system that can be favored over the others as in the case of grab sampling. In the following, four types of continuous radon monitoring will be described. In particular, it is important to note that these continuous monitoring methods can be also used for grab monitoring.

**Scintillation chamber monitor** This instrument is made of a scintillation flask in contact with a photomultiplier. Air is filtered to remove the radon daughters and is drawn continuously through the chamber. For continuous measurements of relatively high concentration of radon, such as in soil gas, an open scintillation cell may be used directly. The open end, usually connected to a tube, is inserted directly into the soil or water. The counting rate of the photomultiplier pulses is monitored continuously and changes proportionally to the radon concentration.

**Diffusion electrostatic method** Ambient air enters the sensitive volume of the instrument by molecular diffusion through the cover made of foam rubber. Radon progenies resulting from the decay of radon within the sensitive volume are attracted to a scintillator detector surface by an electric field (electrostatic collection) established by charging a surface near the scintillator. The rest of the electronics is identical to the scintillator cell method. One such instrument has a hemispherical detection chamber with a volume of several liters. The efficiency of the electrostatic collection depends on the humidity. This

problem can be solved by placing a desiccant in the detection chamber.

**Ionization chamber** The first radon measurements were made with various electrometers, which were primitive ion chambers. Most of the improvements in ion chambers over the years have been in the associated devices or electronics. Since the early applications of the ion chambers, the most important problem to be solved was the discrimination of the radon signal from that of the  $\gamma$ -radiation. The earlier system with paired chambers allowed automatic subtraction of background. One chamber, filled with air and sealed, responded to external  $\gamma$ -radiation. This response was subtracted from that of the chamber containing the sample. The present generation of ion chambers is based on fast pulse measurement rather than total ionization. In this case, pulse discrimination eliminates any  $\beta$ - or  $\gamma$ -response.

In this latter method air is introduced to an ionization chamber after being filtered to remove airborne radon progenies. The current in the chamber is proportional to the radon concentration. The lower detection limit depends on the volume of the ionization chamber and can be as low as  $0.5 \text{ Bq m}^{-3}$ . Ionization chambers are very complex laboratory instruments typically used as reference standards for their accuracy. In some laboratories, the ionization chambers are used as a standard for calibrating other instruments.

**Two-filter methods** This method consists of a two-filter tube with a scintillation phototube detector placed in front of the exit filter. The air is drawn continuously through the tube. The first filter removes all the radon decay products from the sampled air. This air is then passed through a long decay tube, where daughter products are allowed to develop and are collected on a second filter, the activity of which is proportional to the radon concentration in the sampled air.

The exit filter can be fixed or can be advanced automatically at preset time intervals. Sensitivity

depends mainly on the volume of the tube. For volumes of the tube between 1 and 1000 l the sensitivity ranges from thousands of  $\text{Bq m}^{-3}$  to  $0.7 \text{ Bq m}^{-3}$ .

### Integrated Sampling Methods

The most widely used integrating radon monitors are based on totally passive devices that present uniquely attractive characteristics for large-scale surveys. Totally passive devices can be successfully obtained for radon-only measurements in which radon diffuses in a detector housing and the radiation from the radon and its progenies is directly registered by passive types of detectors. These devices can be divided into two broad categories, consisting respectively of diffusion and permeation samplers (Figure 3). The upper part of Figure 3 shows the diffusion sampler, which consists of a tube with a detector located at one end of the diffusion zone formed by the tube. The other end of the diffusion tube is generally open to the atmosphere. By using a sufficiently long tube (with a length greater than 30 cm), the thoron decays before it reaches the sensitive volume of the detector.

The most popular geometry for the detection housing has been the cup-type container closed at one end with a porous filter such as fiberglass, a non-wetting cloth, or a microcore paper filter. These porous filters always ensure that aerosol radon daughters will not enter the sensitive volume of the detector, but they may not be efficient discriminators of thoron gas and water vapor.

A relatively more efficient way to eliminate the thoron and water vapor is to use a polymeric membrane (namely a polyethylene film a few tens of

micrometers thick), in which the gas radon must first dissolve and then diffuse. These devices are referred to as permeation samplers (Figure 3). In particular, a permeation sampler can be simply formed by a heat-sealed plastic bag made of polyethylene, as shown in the lower part Figure 3. Enclosed in the bag are two track detectors held 2 cm apart by an aluminum or plastic spacer. The aluminized plastic films (referred to as degrader in Figure 3) are used to optimize the detector responses to the  $\alpha$ -particles from radon and its progeny.

In principle, different types of passive detectors can be used such as thermoluminescent materials, electret devices, and solid-state nuclear track detectors.

**Solid-state nuclear track detectors** For large-scale survey of long-term integrated radon measurements, the track detectors have the most favorable characteristics. For this reason they have been extensively applied in different national surveys for determining the annual average concentration of indoor radon. When compared to thermoluminescent materials and electrets, track detectors register  $\alpha$ -particles with high sensitivity and selectivity, with no response to lightly ionizing radiation ( $\gamma$  and  $\beta$ ). Several detector materials for the registration of  $\alpha$ -particles have been developed. The most suitable are, respectively, poly allyl diglycol-carbonate (known as CR-39, acronym of Columbia Resin 1939), cellulose nitrate (LR-115 from Kodak), bisphenol-A-polycarbonate (Makrofol from Bayer AG).

Alpha particles penetrating the material cause damage channels of near-atomic dimensions. Upon etching, the damage regions are enlarged to the point that they can be easily seen under the microscope. By counting the tracks in a given area, the exposure of the detector to  $\alpha$ -producing nuclides may be determined.

**Electret ionization chambers** A more recent application of the primitive total ionization chambers (such as the electroscopes used, for example, by Rutherford in the early 1900s), is based on the use of an electret, which holds a charge over a long period and is discharged by exposure to radiation. The loss of a charge is then measured by an electrostatic voltmeter and related to radon exposure through a calibration process. The chamber also responds to  $\gamma$ -radiation and the total signal must be corrected for this response. At average radon concentrations and  $\gamma$ -levels, the two signals are approximately equal. When used as a screening technique for short-term measurements, the assessment of the  $\gamma$ -exposure can be estimated with any available instruments, such as Geiger counter.

**Figure 3** Diffusion and permeation radon samplers: (A) diffusion sampler, (B) permeation sampler, and (C) plastic bag permeation sampler.

However, for the long-term measurements required for the assessment of human exposure, paired chambers must be used in order to ensure the accurate discrimination of the radon signal from that of the  $\gamma$ -background.

**Activated charcoals** Passive radon measurements can be achieved without a passive detector by absorbing radon with activated charcoal, which is analyzed by  $\gamma$ -ray spectrometry at the end of the exposure. These charcoal-based radon monitors are sufficiently sensitive for the assessment of short-term integrated (less than 1 week) radon exposures. They have been widely applied for screening surveys. Unfortunately, because of the 3.825 day half-life of  $^{222}\text{Rn}$ , the exposure period cannot be longer than 1 week and the detector must be analyzed in the laboratory soon after the exposure. For the same reason, this technique does not provide a true integration, but a response more closely related to the last day or two of exposure.

### Measurements of Airborne Radon Decay Products

For what concerns the techniques for the measurement of radon decay products, they are similar in principle to those discussed for airborne radon gas. As with the case of radon, the devices can be separated into the categories of those representing grab samples, continuous measurements, and integrations. Radon decay products are simpler to measure by instantaneous or grab sampling while radon gas measurement is easier using continuous or integrated sampling.

Knowledge of the average concentration of each of the radon decay products is important for the evaluation of the potential hazard. The unit 'working level' (WL) was first introduced to measure the concentration of short-lived radon daughters in the air of uranium mines and was also eventually applied for the assessment of the radon daughters in dwellings. One WL can be represented by any combination of short-lived radon progeny in 1 l of air that will result in the emission of  $1.3 \times 10^5$  MeV of potential  $\alpha$ -energy from the radioactive decay. The term potential refers to the fact that a given atom has a 'potential' to produce a certain amount of energy, if it decays through the rest of the decay chain. The WL avoids the complexity of specifying individual concentrations of each decay product and measures the exposure rate to the total  $\alpha$ -energy from  $\alpha$ -particles in 1 l of air. For this reason the measurement of WL has been appealing historically, since it only requires an air sample filtered for 5 min followed by a single  $\alpha$ -count.

The cumulative exposures for miners have been based on the unit 'working level month' (WLM),

which represents the exposure to one 'WL' for one 'WM' (based on 170 working hours). A better way to express the activity of the radon decay products is the potential alpha energy concentration (PAEC), which is the sum of all the potential  $\alpha$ -energies in a volume of air, divided by the volume of that air. A common unit for this quantity is  $\text{J m}^{-3}$ .

A typical evaluation of PAEC requires a filtered air sample and three subsequent  $\alpha$ -counts. The  $\alpha$ -spectrometry can replace the  $\alpha$ -counter in the detection process.

The PAEC can be readily calculated once the activities of the individual radionuclides have been determined from measurements. Direct measurements of the concentrations of all short-lived decay products of  $^{222}\text{Rn}$  are difficult and limited. They are estimated from considerations of equilibrium (or disequilibrium) between  $^{222}\text{Rn}$  and its decay products. An equilibrium factor  $F$  is defined that permits the exposure to be estimated in terms of the PAEC from the measurement of radon gas concentration. This equilibrium factor is defined as the ratio of the actual PAEC to the PAEC that would prevail if all the decay products in each series were in equilibrium with the parent radon. However, it is simpler to evaluate this factor in terms on an equilibrium equivalent radon concentration, EEC. This quantity, EEC, represents the activity concentration of the radon gas that would have to exist in complete equilibrium with the decay products if the short-lived decay products had the same PAEC as in the nonequilibrium mixture. The units of EC are  $\text{Bq m}^{-3}$ .

The equilibrium factor is then given by

$$F = \text{EEC}/C_m$$

where  $C_m$  is the measured concentration of the radon gas.

It is important to bear in mind that the EEC depends only on the concentrations of the decay products (as only these are considered to be radiobiologically important) and is given by

$$\text{EEC} = 0.105C_1 + 0.515C_2 + 0.380C_3$$

where  $C_1$ ,  $C_2$ , and  $C_3$ , are the activity concentrations of the decay products, namely  $^{218}\text{Po}$ ,  $^{214}\text{Po}$ , and  $^{214}\text{Bi}$ , respectively. The constants are the fractional contributions of each decay product to the total potential  $\alpha$ -energy from the decay of unit activity of the gas. In this way, a measured radon concentration can be converted to an EEC directly proportional to PAEC. This provides a measure of exposure in terms of the product of concentration and time. The EEC can be converted to the PAEC, when desired, by the

relationship:

$$1 \text{ Bq m}^{-3} = 5.56 \times 10^{-6} \text{ mJ m}^{-3} = 0.27 \text{ mWL}$$

Many measurements have been made of  $^{222}\text{Rn}$  and decay product concentrations, allowing estimates to be made of the magnitude of the equilibrium factor to be estimated in terms of both typical values and range. In general, it is unusual to find equilibrium factors less than 0.2, even in well-ventilated rooms or mines. For this reason, it is common practice to measure the concentration of radon gas, which is then used to infer the concentration of its decay products by using a known value for the equilibrium factor. This is highest for outdoor air, followed by those of indoor air and air in mines.

## Radon Measurement in Water, Soil, and Other Solid Matrices

Radon measurements in water, soil, and other solid materials are of interest for geoscientific or geoengineering purposes. Using  $\gamma$ -ray spectrometry it is possible to determine the radon concentration in samples of water, soil, and other solid materials by counting  $\gamma$ -rays from radon decay products, with particular regard to 1.76 MeV  $\gamma$ -rays from bismuth-214. This method, in addition to its low sensitivity, has the disadvantage of requiring two measurements 4 weeks apart. This is because the original radon concentration can be distinguished from the  $^{226}\text{Ra}$  concentration by repeating the analysis after at least 4 weeks. At this later time the original radon will have virtually all decayed and the only remaining radon is that in secular equilibrium with  $^{226}\text{Ra}$ . In other situations where the uranium mineral is resistant to weathering, the radium will tend to be in secular equilibrium with the uranium. In such minerals the radon loss is generally low and  $\gamma$ -ray spectrometry measurements give a good indication of both the radium and the uranium content.

The most common methods for measuring radon in soil and water are based on measurement of the radon gas after it has been separated from the host environmental sample by extraction and/or diffusion processes. Extraction of the radon sample is achieved by pumping gas from the soil using a rigid hollow tube. This is hammered into the ground to a convenient depth, causing minimum disturbance of the soil profile. The detection of radon is obtained by using the scintillation flask (Lucas cell) in a way similar to the grab sampling method. Radon measurements in soil can also be obtained by simply placing the detector in the ground at a depth of 0.5–0.7 m.

These measurements of soil radon by detectors in the ground are of interest when long-term

monitoring is employed to overcome the problem of temporal variation in the concentration of radon. Different detectors can be used, the choice of which depends on the particular application. Real-time detectors such as zinc sulfide scintillators or semiconductors are used when the time dependence of the radon concentration in soil is needed for a limited number of places. For a large-scale survey, the most popular radon monitoring devices are based on the track detector enclosed in the cup-type geometry, as described above.

The measurement of the radon content of water is based on extraction processes that exploit the high partition coefficient of radon either between gas and water or between organic liquid scintillators and water. In particular, by introducing fine gas bubbles to water, it is possible to extract radon very efficiently. Radon is thus bubbled out from water and collected in a Lucas cell. The detection limit for this method is very low,  $\sim 50 \text{ Bq m}^{-3}$ .

An alternative method requires the use of immiscible liquid scintillators. In this method, 5–10 ml of toluene scintillator is added to 10 ml of water in a glass vial and shaken vigorously. Because of the very large partition coefficient of radon between water and organic liquid scintillators, radon is effectively extracted from water and detected by a liquid scintillator counter. The detection limit is  $\sim 370 \text{ Bq m}^{-3}$  ( $10 \text{ pCi l}^{-1}$ ) for a 40 min counting time. This method makes it possible to obtain large-scale counting with automation as required for determining radon in a large variety of water samples. As for the measurement in soil, radon can be monitored under water simply by placing the detector directly in the water. This system has been applied to the monitoring of radon in the ground below the water table.

## Radon Flux Measurements

Radon flux measurements are important for the assessment of the transfer of radon across the interface between a solid phase and the atmosphere. The solid may be the soil, rocks, building materials, or other substances, while the atmosphere may be that of a closed laboratory vessel, a building, or the outdoor air. A variety of methods are available for measuring radon flux in the laboratory and in the field. These methods involve the use of various techniques described above for the assessment of the radon concentration.

### Laboratory Methods

Methods for laboratory measurements of soils and building materials are generally based on placing a sample of the material in a closed chamber and sampling the air of the chamber.

## Field Methods

Among the different methods available, the most applicable for the field measurements are the accumulation method and the adsorption method.

The accumulation method was one of the earliest procedures and consists, basically, of placing the open end of a vessel on the surface being measured. This method requires the use of a suitable sized container, ranging in volume from a few liters up to as much as 220 l. The radon concentration inside the vessel is then measured, either at some selected time or serially over a period of several hours. The requirements for the accumulation method are that the accumulation time is short compared with the 3.82 day half-life of  $^{222}\text{Rn}$ , that the concentration in the vessel is lower (perhaps 10% or less) than that in the solid material, and that the measuring device does not significantly affect the radon exhalation.

The adsorption method involves the use of an activated charcoal canister placed in close proximity to the solid surface. The canister procedure is simple, and the sampler can be readily sealed to vertical surfaces with modeling clay or flexible caulking materials. However, the small sampling area of the canister results in poor sensitivity. The LLD is  $\sim 2.5 \text{ Bq}$ , which amounts to a flux of  $\sim 4 \text{ mBq m}^{-1} \text{ s}^{-1}$  for a 1 day exposure, while the LLD of the accumulation method can easily be 10 times smaller.

## Glossary

Activity	The rate of atomic disintegration (units: Becquerel or Curie).
Becquerel (Bq)	A unit used to describe the rate of radioactive decay. One Becquerel equals one disintegration per second.
Curie (Ci)	An old unit used to describe the rate of radioactive decay. One Curie equals $3.7 \times 10^{10}$ disintegrations per second.
Decay product	A nuclide resulting from the radioactive disintegration of a radionuclide, formed either directly or as the result of successive transformations in a radioactive series. A decay product may be either radioactive or stable.
Decay series	The consecutive members of a radioactive family of elements. A complete series commences with a long-lived parent such as $^{238}\text{U}$ and ends with a stable element such as $^{206}\text{Pb}$ .
Equilibrium-equivalent concentration (EEC)	The EEC of a nonequilibrium mixture of short-lived decay products in air is that activity concentration of the parent gas in radioactive equilibrium with the concentrations of its short-lived decay products that have the same PAEC as the nonequilibrium mixture. Units are $\text{Bq m}^{-3}$ .
Equilibrium factor	An adjustment used in converting from $\text{Bq m}^{-3}$ ( $\text{pCi l}^{-1}$ ) to working level concentration, which takes into account the possible absence of radioactive equilibrium between radon and its decay products.
Radioactive equilibrium	A state in which the rate of formation of atoms is equal to the rate of their disintegration by radioactive decay, so that the amount of the element or isotope is constant.
Flux measurements	Measurements made to determine how much radon is released into an enclosure

	from a source. They are used to determine the rate at which radon emanates from building materials.		
Half-life	The time it takes for one-half of any quantity of identical radioactive atoms to undergo decay.	Working level (WL)	A measure of decay product concentration that indicates the extent of $\alpha$ -particle release from short-lived products. Also a measure of the total $\alpha$ -activity in air.
Potential alpha energy (PAE)	The total energy emitted during $\alpha$ -decays if a quantity of radon decay		

## Uranium

### Introduction

Uranium is a radioactive element that is ubiquitous in the environment, with typical crustal and seawater concentrations of  $2.7 \text{ mg kg}^{-1}$  and  $3.0 \mu\text{g l}^{-1}$ , respectively. Uranium-238 and  $^{235}\text{U}$  are primordial isotopes and their decay leads to the formation of series of daughter radioisotopes, amongst which is  $^{234}\text{U}$  (Figure 1). The natural isotopic ratio of  $^{238}\text{U}$ : $^{235}\text{U}$ : $^{234}\text{U}$  is 99.2745:0.7200:0.0055, and other isotopes (Table 1) are produced by nuclear processes.

Uranium displays multiple oxidation states from +3 to +6, with +4 and +6 being the most common. Uranium(IV) is largely insoluble, as it reacts readily with particle surfaces. Uranium(VI), on the other hand, exists as a di-oxo cation,  $\text{UO}_2^{2+}$  in

solution, which forms stable complexes with oxygen-containing ligands, such as carbonate. This is seen in the high solubility of  $\text{UO}_2^{2+}$  as anionic carbonate complexes in seawater (e.g.,  $\text{UO}_2(\text{CO}_3)_2^{2-}$ ).

The main use of uranium is as nuclear fuel, with a lesser role in nuclear weapons, and its by-product, depleted uranium, is used in conventional weapon heads. Uranium oxides containing  $^{235}\text{U}$  enriched to  $\sim 4\%$  are the most common type of nuclear fuel, although metallic uranium with the natural isotopic ratio of uranium is also used in older technologies (e.g., Magnox). The fuel is bombarded with neutrons to induce fission but, as this process is not 100% efficient and high-energy neutrons result in neutron capture,  $^{236}\text{U}$  is also produced. The production and use of nuclear fuel results in significant changes to the natural isotope ratio, and the isotope ratio is therefore an important tool in identifying anthropogenic enhancement of uranium in the environment over variable natural concentrations. Isotope ratio measurements of natural uranium can also be used to examine environmental processes, for example, by using solubility differences between uranium and thorium, which is a precursor of  $^{234}\text{U}$  (Figure 1).

The study of uranium covers a wide range of interests, from natural systems with low anthropogenic inputs, to mining spoil heaps and contaminated environments, to quality control of fuel production and waste management. Analytical requirements are therefore highly varied with the need to measure uranium in different phases, from ultra-trace to high concentrations, from total uranium concentrations to high precision isotope ratios. The cost of analysis and availability of instrumentation must also be taken into consideration when selecting the appropriate analytical technique.

A range of sample types require radiochemical separation of uranium from the sample matrix and removal of elements that interfere with accurate

### Introduction

Uranium is a radioactive element that is ubiquitous in the environment, with typical crustal and seawater concentrations of  $2.7 \text{ mg kg}^{-1}$  and  $3.0 \mu\text{g l}^{-1}$ , respectively. Uranium-238 and  $^{235}\text{U}$  are primordial isotopes and their decay leads to the formation of series of daughter radioisotopes, amongst which is  $^{234}\text{U}$  (Figure 1). The natural isotopic ratio of  $^{238}\text{U}$ : $^{235}\text{U}$ : $^{234}\text{U}$  is 99.2745:0.7200:0.0055, and other isotopes (Table 1) are produced by nuclear processes.

Uranium displays multiple oxidation states from +3 to +6, with +4 and +6 being the most common. Uranium(IV) is largely insoluble, as it reacts readily with particle surfaces. Uranium(VI), on the other hand, exists as a di-oxo cation,  $\text{UO}_2^{2+}$  in

solution, which forms stable complexes with oxygen-containing ligands, such as carbonate. This is seen in the high solubility of  $\text{UO}_2^{2+}$  as anionic carbonate complexes in seawater (e.g.,  $\text{UO}_2(\text{CO}_3)_2^{2-}$ ).

The main use of uranium is as nuclear fuel, with a lesser role in nuclear weapons, and its by-product, depleted uranium, is used in conventional weapon heads. Uranium oxides containing  $^{235}\text{U}$  enriched to  $\sim 4\%$  are the most common type of nuclear fuel, although metallic uranium with the natural isotopic ratio of uranium is also used in older technologies (e.g., Magnox). The fuel is bombarded with neutrons to induce fission but, as this process is not 100% efficient and high-energy neutrons result in neutron capture,  $^{236}\text{U}$  is also produced. The production and use of nuclear fuel results in significant changes to the natural isotope ratio, and the isotope ratio is therefore an important tool in identifying anthropogenic enhancement of uranium in the environment over variable natural concentrations. Isotope ratio measurements of natural uranium can also be used to examine environmental processes, for example, by using solubility differences between uranium and thorium, which is a precursor of  $^{234}\text{U}$  (Figure 1).

The study of uranium covers a wide range of interests, from natural systems with low anthropogenic inputs, to mining spoil heaps and contaminated environments, to quality control of fuel production and waste management. Analytical requirements are therefore highly varied with the need to measure uranium in different phases, from ultra-trace to high concentrations, from total uranium concentrations to high precision isotope ratios. The cost of analysis and availability of instrumentation must also be taken into consideration when selecting the appropriate analytical technique.

A range of sample types require radiochemical separation of uranium from the sample matrix and removal of elements that interfere with accurate

**Figure 1** Early stages of the uranium decay series.

measurement. A number of radiochemical separation techniques exist, notably co-precipitation, ion exchange, and solvent extraction. The application of measurement techniques to uranium will be described after a discussion of the sample preparation and radiochemical methods.

## Sample Digestion

Sample digestion is used to obtain a representative, homogeneous solution, to ensure that the uranium is present in solution as an inorganic complex or ion for the subsequent radiochemical separations, and to allow equilibration with the yield monitor (see below). Thus, liquids, as well as solid matrix samples, are often digested prior to analysis or radiochemical separation. The most common methods are acid digestion and fluxed decomposition. Acid digestion of dried soils, sediments, and foodstuffs often follows dry ashing of the organic matter at 450–550°C. The aggressiveness of the acid employed depends on the sample, and, for example, HF is required to digest silicate minerals while mixtures of HNO<sub>3</sub>, HCl, and H<sub>2</sub>SO<sub>4</sub> are suitable for many matrices. Use of fluoride can result in the formation of insoluble uranium fluorides and therefore fuming perchloric acid or boric acid should be added to prevent this.

In fluxed decomposition, or high-temperature fusion reactions, an accurate mass of sample is placed in a crucible with the flux material. Sodium hydroxide, sodium peroxide, sodium carbonate, and lithium tetraborate have been used for this purpose. The mixture is heated in a furnace or Meker burner until it forms a well-mixed, molten fusion. After cooling, this is dissolved in a dilute mineral acid. This method is arguably the best method for complete digestion, but other methods are used routinely and widely. A negative aspect of fusion is that it results in solutions with high total dissolved solids and potentially leads to contamination by the reagents. Solution-phase samples, such as natural waters, are digested using similar procedures, for example, nitric acid or aqua regia digestions may be used, but HF or fusion would give more quantitative dissolutions if small, recalcitrant uranium-rich particles were present.

The extent to which a digestion procedure brings the uranium into solution cannot be assessed through spiked experiments or addition of a yield monitor, as the spike is not representative of the actual sample. However, there are standard procedures published by the American Society for Testing and Materials (ASTM) and the Environmental Protection Agency (EPA) of the USA. Certified reference materials are also available from the International Atomic Energy Agency/NIST.

## Preconcentration and Separation

Analytical radiochemical procedures routinely use combinations of co-precipitation, solvent extraction, and ion exchange to preconcentrate and isolate uranium from bulk stable elements and potential interferences (e.g., for alpha and mass spectrometric techniques, see Table 1).

### Co-Precipitation

Iron(III) co-precipitation is an effective method for preconcentrating uranium from large-volume samples. An additional benefit is the removal of much of the bulk matrix, for example, salt in seawater. Iron(III) is added in milligram quantities and the pH is raised to ~9 using ammonia solution or sodium hydroxide. The hydrated iron(III) oxide precipitate is separated from the bulk solution by centrifugation or filtration and then dissolved in HCl.

**Table 1** Isotopes, half-lives, and main alpha emission energies of uranium and potential interferences in mass and alpha spectrometric techniques

<i>Element</i>	<i>Isotope</i>	<i>t<sub>1/2</sub> (years)</i>	<i>Main alpha energies/MeV<sup>a</sup></i>
Uranium	<sup>239</sup> U	$4.47 \times 10^{-5}$	Beta
	<sup>238</sup> U	$4.47 \times 10^9$	4.15 (0.23)
			4.20 (0.77)
	<sup>236</sup> U	$2.34 \times 10^7$	4.45 (0.22)
			4.50 (0.78)
	<sup>235</sup> U	$7.04 \times 10^8$	4.37 (0.16)
			4.40 (0.58)
	<sup>234</sup> U	$2.46 \times 10^5$	4.77 (0.71)
			4.72 (0.28)
	<sup>233</sup> U	$1.59 \times 10^5$	4.78 (0.15)
Plutonium			4.82 (0.83)
	<sup>232</sup> U	69.8	5.26 (0.31)
			5.32 (0.69)
	<sup>238</sup> Pu	87.7	5.46 (0.29)
			5.50 (0.71)
Neptunium	<sup>239</sup> Pu	$2.41 \times 10^4$	5.14 (0.15)
			5.16 (0.73)
	<sup>240</sup> Pu	$6.56 \times 10^3$	5.12 (0.27)
			5.17 (0.73)
Thorium	<sup>237</sup> Np	$2.14 \times 10^6$	4.77 (0.25)
			4.78 (0.48)
Radium	<sup>232</sup> Th	$1.41 \times 10^{10}$	3.95 (0.23)
			4.01 (0.77)
	<sup>230</sup> Th	$7.54 \times 10^4$	4.62 (0.23)
			4.69 (0.76)
	<sup>229</sup> Th	$7.34 \times 10^3$	4.85 (0.56)
Polonium			4.90 (0.10)
	<sup>228</sup> Th	1.9	5.34 (0.28)
			5.42 (0.72)
Radium	<sup>226</sup> Ra	$1.6 \times 10^3$	4.60 (0.06)
			4.78 (0.94)
Polonium	<sup>210</sup> Po	0.38	5.30 (1.0)

<sup>a</sup>Values in parentheses correspond to emission probabilities.

Other types of co-precipitation are used in the preparation of samples for analysis. For example, cerium(IV) hydroxide, cerium(III) fluoride, and neodymium fluoride can be used to prepare sources for alpha spectrometry (see below). LaF<sub>3</sub> co-precipitation is used in the preparation of samples for uranium measurement by neutron activation analysis (see below).

### Solvent Extraction

Solvent extraction is used on both analytical and industrial scales and utilizes the high solubility of uranium in many organic solvents, in contrast to the low solubility of elements such as iron, thorium, radium, and rare earth elements. Uranium must be present in an ionic form in an aqueous solvent (see sample digestion) as solvent extraction will not extract colloids or complexes. Separation funnels or counter-flow systems can be used, with a higher efficiency and throughput possible using the counter-flow approach.

Tertiary amines can be used to extract uranium from chloride or sulfate media, e.g.,

This process coextracts molybdenum, vanadium, and zirconium, but uranium can be separated from these elements by using a selective back-extraction process into the aqueous phase. For example, sodium chloride will strip uranium, while carbonate will remove uranium and molybdenum. This is relevant if, for example, the uranium will be quantified by titration (see below).

Tributyl phosphate (TBP) in paraffinic diluent can be used to isolate uranium and plutonium from a nitric acid ( $\sim 6 \text{ mol l}^{-1}$ ) medium, with uranium extracted as a neutral uranium nitrate complex:

Back-extraction can be achieved by washing with dilute nitric acid.

### Ion Exchange

Ion exchange is a method of separating complexes or ions in solution as a function of their differential attraction to a charged stationary phase. The stationary phase is held in a column and the mobile phase is changed to manipulate the speciation of the elements of interest. Anion exchange is a convenient method for removing bulk and trace interferences from the actinides, partly because of their complex solution chemistry.

Ion exchange resins are named according to the manufacturer, the purity, the resin type, and the cross-linkage of the resin beads. So, for example,

BioRad AG1-X8, refers to Bio-Rad's version of analytical grade type '1' resin with a cross-linkage of 8%. Type 1 resin has the functional group  $\text{R-CH}_2\text{N}^+(\text{CH}_3)_3$ , and is commonly used for uranium separation, as it has a high specificity for anionic chloride, sulfate, and oxalate complexes of uranyl over those of other metal cations. Cation exchange resins, on the other hand, are not used for uranium separations because of their low specificity. Using type 1 resin as an example, a high chloride concentration is required for the formation of negative uranyl chloro complexes, e.g.,  $[\text{UO}_2\text{Cl}_4]^{2-}$ . Therefore, uranium will not adhere to a type 1 resin in  $1 \text{ mol l}^{-1}$  HCl, but has a high affinity for the resin in  $9 \text{ mol l}^{-1}$  HCl. Neptunium(IV) also adheres to the resin in  $9 \text{ mol l}^{-1}$  HCl, but americium, plutonium, radium, and thorium pass through. Washing the column with  $8 \text{ mol l}^{-1}$  HNO<sub>3</sub> elutes uranium as  $[\text{UO}_2(\text{NO}_3)_2]$ , while retaining neptunium on the column. Other possible complexants include oxalate ( $0.5 \text{ mol l}^{-1}$ ), which causes the formation of anionic uranyl complexes that are retained on the resin, and a mixture of  $6 \text{ mol l}^{-1}$  HCl and  $1 \text{ mol l}^{-1}$  HClO<sub>4</sub>, which elutes uranium. The potential analytical interferences can therefore be removed by the differences in speciation in different solutions, and their affinity for the anion exchange resin.

### Extraction Chromatographic Resins

Specific extraction chromatographic resins have been developed for the isolation of actinides. They are used in a manner similar to ion exchange resins, but function as immobilized solvent phases, and thus work in the same way as solvent extraction. These resins have high specificities for the analytes of interest and are directed at solving problems associated with radio-nuclide separations. For example, U/TEVA (Eichrom Industries) is diamylphosphonate sorbed on an inert polymeric substrate, and has been developed for the separation of uranium from other actinides. If an oxidized solution is applied to a U/TEVA column in  $3 \text{ mol l}^{-1}$  HNO<sub>3</sub>, U, Np, and Th adhere to the column, while Pu and Am pass through. Th, Np, and Fe(III) can be completely removed by converting the column to a chloride form with  $9 \text{ mol l}^{-1}$  HCl and then washing with  $5 \text{ mol l}^{-1}$  HCl– $0.05 \text{ mol l}^{-1}$  oxalic acid. A clean solution of uranium can then be obtained by eluting with  $0.01 \text{ mol l}^{-1}$  HCl. Other specialist resins can also be used, for example, TRU.Spec resin (Eichrom Industries).

### Yield Monitors

A yield monitor is an isotope that is added to a sample prior to radiochemical separation and analyzed

postseparation to quantify the yield of the process. Most radiochemical separation techniques have variable recoveries that are influenced by the sample matrix, oxidation state control, and exact chemical and physical conditions. Therefore, a yield monitor is required for quantitation. The most reliable type of yield monitor is an isotope of the analyte that is not present in the sample of interest, because it will behave in exactly the same way as the analyte throughout the procedure. The addition of a yield monitor also compensates for experimental errors such as spills, boiling over, or losses to the beaker when heating to dryness. Yield monitors can be added either prior to or after digestion, since they cannot monitor the effectiveness of a digestion procedure. Dilution of a sample leachate may also be required prior to addition of a yield monitor.

The yield monitor must be measurable without spectral overlap with the uranium in the sample, and so artificial isotopes are used. These are prepared with minimal contamination of natural or environmentally relevant uranium isotopes. Uranium-232 is a suitable candidate for radiochemical preparation for analysis by alpha spectrometry as it has a suitable half-life and an alpha energy that does not interfere with the peaks from the other isotopes. Uranium-233 is preferred for mass spectrometric techniques because it has a long half-life and has few spectral interferences, whereas  $^{232}\text{U}$  is isobaric with  $^{232}\text{Th}$ . Both these yield monitors also function as internal standards for the measurement technique, which lowers the overall uncertainty associated with yield determination and measurement.

## Measurement Techniques

There are a wide range of techniques available for the measurement of uranium. The detection limits of a selection of widely used techniques are summarized in Table 2.

**Table 2** Summary of sample form and approximate detection limits of measurement techniques

<i>Method</i>	<i>Sample form</i>	<i>Approximate limit of detection</i>
Titration	Solution	$0.5\text{ g l}^{-1}$
Spectrophotometry	Solution	$10^{-6}\text{--}10^{-3}\text{ g l}^{-1}$
XRF	Solid	$10^{-4}\text{ g}$
Gamma analysis	Solid or solution	$10^{-5}\text{ g g}^{-1}$
LSC	Solution	From $10^{-8}\text{ g l}^{-1}$
NAA	Solid	From $10^{-12}\text{ g g}^{-1}$
Alpha spectrometry	Deposited on a planchet	$10^{-8}\text{--}10^{-7}\text{ g}$
ICP-MS	Solution	$10^{-15}\text{--}10^{-10}\text{ g}$
AMS	Prepared in matrix	$10^{-17}\text{ g}$

## Total Uranium Analysis

Total uranium can be analyzed by redox titration against acidified potassium permanganate, cerium(IV), or potassium dichromate. Uranium is reduced prior to the titration with zinc amalgam. Dichromate titrations are used to determine uranium concentrations in dissolved uranium metal, uranium ore, or yellow cake ( $\text{UO}_3$ ) samples. There are potential interferences from bismuth, manganese, platinum, silver, vanadium, and zirconium, which must therefore be removed prior to the titration.

Spectrophotometry also provides rapid, cost-effective measurement of total uranium concentrations, at levels down to tens of  $\mu\text{g l}^{-1}$ . In this method, a chelating agent is added to the digested solution to form colored uranium complexes. The most common chelator is 2-(5-bromo-2-pyridylazo)-5-diethylamino-phenol (bromo-PADAP), which may require removal of chromium, vanadium, or phosphate interferences by solvent extraction, prior to analysis.

Various forms of atomic absorption and atomic emission spectrometry are also able to perform rapid analyses of solutions. A high temperature is required to atomize uranium efficiently; therefore, Graphite furnace AAS and ICP-AES have low detection limits of  $20\text{--}30\text{ }\mu\text{g l}^{-1}$ , while Flame AAS has a detection limit of  $\sim 40\text{ mg l}^{-1}$ .

Uranium fluoresces and therefore can be analyzed by XRF. This allows direct analysis of uranium in solid matrices and overcomes the challenges of digestion and separation.

## Radiometric Techniques

Trace analysis of uranium can be carried out using a variety of radiometric techniques. The least sensitive method is gamma analysis of short-lived daughter products, for example, the  $^{234}\text{Th}$  daughter ( $t_{1/2} = 24.1$  days) of  $^{238}\text{U}$ . Short-lived daughter isotopes are in secular equilibrium with their parent isotope, unless they have been chemically separated, and the activity of  $^{234}\text{Th}$  is therefore exactly the same as that of the long-lived parent.

Lower detection limits are achieved using liquid scintillation counting (LSC) with  $\alpha$ - $\beta$  discrimination. The most sensitive system is the photon electron rejecting alpha liquid scintillation spectrometry, which can measure concentrations as low as  $1\text{ mBq l}^{-1}$ . However, other LSC systems have detection limits an order of magnitude or so higher. LSC requires thorough radiochemical separation to remove interfering isotopes, and the interferences are the same as for alpha spectrometry.

Neutron activation analysis is a sensitive technique for uranium analysis, but its use is limited by access

to a research reactor. During neutron bombardment,  $^{238}\text{U}$  is activated to  $^{239}\text{U}$ , which rapidly decays to  $^{239}\text{Np}$  via beta decay. Neptunium-239 has a half-life of 2.36 days, and can be measured by gamma analysis after removal from the reactor. Ultrasensitive delayed neutron counting is also possible with uranium, and this uses a pneumatic transfer system to carry the sample from the neutron flux to a neutron detector for counting after a short decay period (e.g., 20 s). Neutron activation analysis often requires prior radiochemical separation and the techniques described earlier, such as solvent extraction, ion exchange, and co-precipitation, are used typically for this purpose.

Alpha spectrometry has been used widely to measure uranium and is still used to a significant extent today. Direct counting of alpha emissions is achieved using surface-barrier semiconductor detectors. In effect, the detector is able to record the pulse of energy deposited as the alpha particle collides with it, and convert the pulse amplitude to an energy. Alpha particles are emitted with characteristic energies, allowing isotopes to be differentiated. Given that alpha particles have a high linear energy transfer, the uranium should optimally be prepared as an atom thin layer on a planchet, to prevent self-absorption of radiation. The source is then positioned close to the detector under high vacuum, to prevent energy spread of a given type of alpha emission.

With some planchet preparation techniques, peak resolution of 0.004–0.005 MeV can be achieved, and the common method of electrodeposition can allow resolution of  $\sim 0.02$  MeV. Resolution decreases as the peaks increase in size, and this has implications when the specific activity of one isotope is much lower than another. The activity of an isotope is a function of its half-life and percentage abundance. Therefore, the natural activity ratio of  $^{238}\text{U}$ : $^{235}\text{U}$ : $^{234}\text{U}$  is 0.483:0.0225:0.495. The alpha energies of  $^{238}\text{U}$ ,  $^{235}\text{U}$ , and  $^{234}\text{U}$  (Table 1) are resolvable, but it should be noted that when the count times are long enough to obtain a reasonable peak for  $^{235}\text{U}$ , the  $^{234}\text{U}$  and  $^{238}\text{U}$  peaks will be large and will typically have a base width of  $\sim 0.1$ – $0.2$  MeV. This hampers  $^{236}\text{U}$  analysis because of the relatively low activity concentrations of  $^{236}\text{U}$ , and the energies of its principle alpha emissions.

Typical efficiencies of surface barrier semiconductor detectors are 25–40%, and the backgrounds of uncontaminated detectors are close to zero, with a count recorded every few days. This makes it a sensitive technique for most alpha-emitting radionuclides. However, the low specific activity of uranium means that count times can be long (many days or weeks) for low-level samples.

The need to prepare very thin sample sources for counting necessitates a lengthy radiochemical separation procedure to remove bulk elements efficiently, as well as alpha emitters that will interfere with the spectra (Table 1). Radiochemical procedures and sample mounting onto a planchet are variable in efficiency and can be affected by sample-related factors. It is therefore imperative to use a yield monitor for the procedure if quantitation is required. After radiochemical separation the solution is prepared for alpha counting using electrodeposition, co-precipitation and filtration as a thin source, direct evaporation, electrospraying, or vacuum sublimation. If the planchet is contaminated with polonium, the planchet is heated to remove the volatile polonium.

### Mass Spectrometric Techniques

Atom counting techniques are highly sensitive methods for measuring the long-lived uranium isotopes  $^{238}\text{U}$ ,  $^{236}\text{U}$ ,  $^{235}\text{U}$ , and  $^{234}\text{U}$ . It is generally accepted that mass spectrometry is competitive with alpha counting for isotopes with half-lives greater than  $10^3$ – $10^4$  years, given the relationship

$$A = N\lambda$$

where  $A$  is the activity (Bq),  $N$  the number of atoms, and  $\lambda = \ln 2/t_{1/2}$ , with the half-life given in seconds.

However, there is a wide range of mass spectrometric instrumentation and these instruments have detection limits that range over many orders of magnitude. Mass analysis also allows the measurement of isotope ratios. Additionally, isobaric interferences associated with mass spectrometry are typically reduced at the high mass range, making uranium determination possible with limited sample preparation, at least for samples that do not require preconcentration. These factors alongside the rapid sample processing, and high sensitivity of some of these techniques make mass spectrometry an attractive measurement technique for uranium.

Inductively coupled plasma mass spectrometry (ICP-MS), laser ablation ICP-MS (LA ICP-MS), thermal ionization mass spectrometry (TIMS), secondary ion mass spectrometry (SIMS), glow discharge mass spectrometry (GDMS), resonance ionization mass spectrometry (RIMS), and accelerator mass spectrometry (AMS) have been used successfully to measure uranium concentrations and isotope ratios in a wide range of sample matrices. The specific details of the methods are described fully in the relevant sections of this encyclopedia. There are specific advantages associated with each method, which depend on the sample of interest and the information required.

**Figure 2** Mass spectrum of uranium extracted from a soil sample. Each mass was counted for a different time. Each peak was counted over a mass range greater than the peak; therefore, the edge of the neighboring peaks can be seen in the individual mass scans.

Briefly, LA ICP-MS, SIMS, and GDMS are suitable for the direct analysis of trace uranium in solid samples. RIMS offers near complete suppression of interferences. Quadrupole ICP-MS is relatively low cost and the most available. In sector field ICP-MS, the mass resolution can be increased up to 0.02 of a mass unit, which provides an inherent separation of many interferences. All types of ICP-MS can be coupled with a range of sample introduction systems to improve the delivery of sample to the plasma, and thereby increase the sensitivity of the measurement. TIMS provides the best isotope ratio measurements, with typical precisions of 0.25%, and AMS offers the lowest detection limits, in the region of  $10^4$  atoms, and effective reduction of interferences.

While  $^{238}\text{U}$  and, to a lesser extent  $^{235}\text{U}$ , are readily determined by all forms of mass spectrometry, there are challenges related to their relative concentrations. For example,  $^{238}\text{U}$  is orders of magnitude higher than any other isotope of uranium. When other isotopes are measurable, the  $^{238}\text{U}$  peak is very large and tailing from this peak can interfere with measurements at masses close to 238. **Figure 2** shows an ICP-MS spectrum in which the  $^{238}\text{U}$  count rate exceeds the capabilities of the electron multiplier detector. The peak tails into  $m/z$  236 and obscures any  $^{236}\text{U}$  present; however, it does not obscure the  $^{235}\text{U}$  peak. It should be noted that the count times for each peak were not equal.

Instruments have been developed to improve isotope ratio measurements, increase sensitivity, and reduce the effects of tailing, by reducing the energy

spread of the ion beam. Sector field ICP-MS uses a double-focusing system to achieve the lower energy spread, resulting in high sensitivity and highly accurate isotope ratio measurements, especially when fitted with a multicollector. Newer developments in ICP-MS such as collision cell ICP-MS improve sensitivity and isotope ratio measurements over quadrupole instruments by colliding the atoms prior to deflection; thus  $^{236}\text{U}$  can be measured in the presence of  $^{238}\text{U}$  at ratios  $3 \times 10^{-7}$ , and with a precision of 0.33%. The expensive and uncommon technique of heavy isotope accelerator mass spectrometry can deliver isotope ratio measurement of, for example,  $^{236}\text{U}$  and  $^{235}\text{U}$ , at a ratio of  $10^{-6}$ .

### Introduction

Radiotracers have a variety of applications, the main uses being in engineering, medicine, and environmental sciences. Despite the variety of applications the same basic principles are used. This article gives an introduction to the principles of tracer techniques and measuring devices. Applications in industry, chemical, and physical research and clinical work as well as in food and environmental analysis are presented.

### Basic Principles of Radiotracers and Their Uses

A tracer defined in the simplest way is a substance that can be traced. It has some property that distinguishes it from its environment and makes it possible to detect it above the background.

Tracers are usually divided into inactive tracers (e.g., dyes) and radiotracers, i.e., radioactive substances. One advantage of radioactive tracers is their relatively easy and accurate detection compared to inactive tracers. Disadvantages include the radiation hazard involved and the expensive instrumentation demanded. Because of the radiation hazard the use of radiotracers is controlled in most countries. In order to minimize risks, an activity as low as possible should be used and short-lived isotopes are preferred.

The simplest form of tracer technique involves tracking the tracer or just measuring the tracer content in a sample. In these applications the tracer substance usually represents a larger amount of material, so by observing the tracer the bulk behavior can be studied. A homogeneity measurement can be achieved by measuring the tracer content of several samples. In medical work the presence or absence of the tracer in some location may be significant.

Measurement of the residence time distribution as the tracer passes through a system is another basic principle of tracer techniques. Typical applications are measurement of the transit time of a tracer pulse, a method applied in flow measurement, as well as measurement of a system response to a transient, a method that gives valuable information on a system, mainly industrial and environmental processes.

Isotope dilution is a method that can be utilized in mass and volume determination as well as in flow measurement. The method takes advantage of the decreased activity per volume or mass as a known amount of tracer is diluted to a larger volume or mass of inactive substance.

The main applications of radiotracers are in the fields of industry and chemical and physical research as well as in medicine.

The main applications of radiotracers in industrial work are:

- distinguishing and tracking of materials;
- flow rate measurement;
- study of process behavior;
- detecting and searching for leaks and cracks;
- determination of mass and volume;
- wear studies; and
- measuring mixture homogeneity.

Methods used in physical and chemical research make use of the same basic principles as the industrial applications. However, the work is of a slightly different character; some applications are mentioned below.

In clinical work, radiotracers are used in diagnostics and therapy as well as in pharmacokinetic and metabolic studies.

Applications in food and environmental analyses use the same principles as industrial and clinical applications. Food analysis has much in common with pharmacokinetic studies and environmental analysis is often related to industrial studies.

Another use of radiotracers, not clearly classified in the applications mentioned above, is age determination based on radioisotopes. Age determination is mainly applied in geological surveys, although some applications are also found in industry and food analysis.

### Counting Techniques

#### Detector Types

There are three different main types of radiation detectors. These are detectors based on gas ionization, scintillation detectors, and semiconductor detectors.

Detectors based on gas ionization are the ionization chamber, proportional counter, and Geiger–Müller counter. These devices measure the electric current pulses induced by radiation between electrodes in a gas-filled chamber. The ionization chamber has a low

bias voltage and can be used to measure only high-energy radiation. The current induced is proportional to the intensity of radiation. The ionization chamber can be connected to an electrometer in order to produce a time-averaged output proportional to the radiation dose rate. The proportional counter has a higher bias voltage and is energy-selective. The Geiger-Müller counter has a high bias voltage and one radiation quantum induces a high, constant-amplitude electric pulse.

The semiconductor detector is also based on ionization. The ionization takes place in the p-n junction of two semiconductor materials. At room temperature the signal-to-noise (S/N) ratio of semiconductor detectors is poor but increases when the detector is cooled, e.g., by liquid nitrogen. The semiconductor detector has a very good energy resolution.

Scintillation detectors are based on luminescence. Some materials have the special property that as they absorb a radiation quantum, a light flash is produced. The intensity of the flash is proportional to the radiation energy. The flash is amplified with a photoelectron multiplier. The energy resolution, though poor when compared with that of semiconductor detectors, is sufficient for many purposes.

### Counting Equipment

A basic radiation measuring system consists of the detector, a high-voltage power supply for bias voltage, a preamplifier, and a power supply for the preamplifier and signal amplifier. A pulse height discriminator is used to decrease the low-energy noise from the detector and the amplifier.

A rate meter generates a time-averaged number of pulses obtained from the signal amplifier. Rate meters are normally used in portable radiation dose rate monitors with a Geiger-Müller counter or a scintillation detector. A sealer is a device counting the number of pulses in a selected time.

Pulse height analyzers are used more extensively for analysis purposes. The pulses from the amplifier are proportional to the radiation energy and can be analyzed either with a single-channel or a multichannel analyzer. A single-channel analyzer is used to count pulses in a certain energy range. A multichannel analyzer produces the energy spectrum of the measured radiation. Multichannel analyzer devices are usually expensive and their portability is restricted by the demand for cooling of the semiconductor detectors. Their use is necessary in some tracer applications, e.g., if a small amount of tracer has to be detected in the presence of strong background

radiation or if tracers with different energies have to be discriminated.

In many tracer applications it is not necessary to measure the absolute concentration of the tracer in a sample or in a material flow. In such cases a scintillation detector accompanied by a single-channel pulse height analyzer is a sufficient device.

A  $\gamma$ -camera, also referred to as a scintillation camera or Anger camera, is a device used mainly in clinical work. It consists of a large scintillation crystal, to which radiation is directed through a large pinhole collimator, and a matrix of photoelectronic multipliers. When a radiation-induced flash occurs in the scintillation material, the point of flash is calculated based on the intensity distribution registered by the photoelectron multipliers. Energy discrimination is used to decide whether the pulse was induced by the tracer or background. Modern computer techniques provide a means of monitoring the movements and accumulation of the tracer (**Figure 1**).

Positron emission tomography (PET) uses a device, in which several detectors are positioned circularly around the object. When a positron is emitted it almost immediately annihilates with an electron. As a result of the annihilation two  $\gamma$ -quanta are ejected in opposite directions. As two detectors detect simultaneously these 511 keV  $\gamma$ -quanta the occurrence is with a certain probability due to a positron emission at the line connecting the two detectors. As several occurrences at different angles are recorded an image of the object can be constructed.

**Figure 1** False-color scintigram of the human spine and ribs, revealing secondary cancers (metastases) in the vertebrae arising from a primary cancer of the prostate gland. A scintigram ( $\gamma$ -camera scan) is a record of radioactive emissions from an isotope (in this case,  $^{99m}\text{Tc}$ ) that is selectively absorbed by bone when injected into the body.  $\gamma$ -ray scintigraphy is frequently used to screen cancer patients for signs of secondary disease, often after their primary cancer has been treated. Here, the metastases appear as the pink and white 'hot spots' in the thoracic spine. (Reproduced from CNRI/Science Photo Library.)

## Counting Statistics

Radioactive decay is a statistical process. The number of decays per unit time obeys the Poisson distribution. The number of counts measured by the detector and the counting equipment is proportional to the activity of the sample. Factors affecting the proportionality are self-absorption by the source, absorption and scattering between the source and the detector, the efficiency of the detector, and the measuring geometry. The proportionality between the absolute sample activity and measured count rate is not necessary linear, but the assumption of linearity is sufficient in many cases.

An important characteristic of the Poisson distribution is that the mean and variance are equal. Thus, if  $N$  counts are measured in an arbitrary time  $T$ , then the mean deviation for the number of counts can be estimated as  $\sqrt{N}$ . If a background measurement shows  $N_b$  counts in time  $T$ , then  $N - N_b$  counts are due to the sample. The mean deviation for this is  $\sqrt{(N + N_b)}$ . The relative error of radiation measurement can be decreased by increasing the number of counts. Two alternatives are obvious: increasing the amount of radioactivity and increasing the counting time.

## Radiotracers in Industry and Research

### Distinguishing and Tracking of Materials

Many tracer studies are intended to give only qualitative information such as information about the material of which an object is made or the location or route which the material or object is following. An example of this kind of application is the so-called pipe-pig used to clean long pipelines. A radiation source can be installed in the pig in order to localize it in case of blockage. In the early days of the industrial applications of radioisotopes the source in a pipe-pig was typically a 10 GBq cobalt-60 source. Nowadays more sensitive radiation detectors are used and short-lived radiotracers like manganese-56 or sodium-24 with activities of  $\sim 1$  GBq are used. These are installed in the pig each time just before the use.

Tracers have also been used to mark some special-purpose or special-quality materials, like stainless-steel alloy tubes for the heat exchangers of nuclear reactors.

### Flow Rate Measurement

Tracers can be used in flow rate measurement in order to calibrate existing flow meters or to measure flows where flow meter installation is difficult and the flow rate has to be known only temporarily.

**Figure 2** Flow measurement by the transit time method; flow rate is determined using the transit time ( $\tau$ ) of a tracer pulse between the two detectors.

Flow rate measurement with radiotracers is applicable to liquid and gaseous flows as well as to flows of solids.

The 'transit time method' is based on measuring the residence time of a tracer pulse between two measuring points. The flow rate  $Q$  is

$$Q = V\tau^{-1} \quad [1]$$

where  $V$  is the volume between the measuring points and  $\tau$  is the residence time. The transit time method is illustrated in Figure 2. The method is especially suitable for pipe flows. In order to compensate for the effects of radial velocity profile on the residence time, the flow must be turbulent and the tracer must be injected at least  $100 \times D$  ( $D$  is the pipe diameter) before the measuring interval in order to guarantee mixing across the pipe cross-section.

In the 'dilution method' tracer solution is fed into the main flow at a known flow rate  $q$ . The tracer concentration is measured from the original tracer solution and samples taken from the main flow. When the initial concentration is denoted by  $C_0$  and the sample concentration by  $C_1$ , it can be stated that

$$C_0 q = C_1 (Q + q) \quad [2]$$

Thus, the main flow rate  $Q$  is

$$Q = q \left( \frac{C_0}{C_1} - 1 \right) \approx q \frac{C_0}{C_1} \quad [3]$$

where the last identity is due to the fact that usually  $Q \gg q$ , and, thus, also  $C_0 \gg C_1$ . The method is illustrated in Figure 3.

'Pulse dilution methods' are based on a known amount of fed tracer and sampling from the main flow. At each point of the main flow downstream,

**Figure 3** Flow measurement by the dilution method; flow rate is determined by the dilution of the tracer solution in the main flow.

there is the relationship

$$\begin{aligned} A &= Q \int_0^{\infty} C(t) dt \\ &= C_0 V \end{aligned} \quad [4]$$

where  $A$  is the total amount of tracer,  $V$  is the volume of fed tracer,  $C_0$  is the concentration of the initial solution, and  $C(t)$  is the tracer concentration in the main flow at time  $t$ . The integral term can be determined, e.g., by continuous sampling during a time  $T$ , assuming that all tracer has passed the sampling location during this time. The tracer concentration of the sample is the average concentration:

$$\bar{C} = \frac{1}{T} \int_0^T C(t) dt \quad [5]$$

and the main flow rate can be determined as

$$Q = \frac{V C_0}{T \bar{C}} \quad [6]$$

In dilution methods the measurement of absolute concentrations is avoided by measuring count rates from the samples using a constant geometry.

### Study of Process Behavior

The determination of the residence time distribution of a process is probably the most used industrial application of radioactive tracers. The residence time distribution is the probability distribution of the time a piece of material is likely to spend in the process. The knowledge of this distribution is important when designing the process, as well as when the process is operated, in order to optimize the process operation conditions. The residence time distribution

can also be utilized in modeling many single- or multiphase flow processes.

The most straightforward way to determine the residence time distribution is to measure the system response for a short tracer pulse. If the system is closed, i.e., no back-mixing occurs at the process entrance and exit, the measured tracer concentration curve, when scaled to unity, is the residence time distribution.

### Detecting and Searching for Leaks and Cracks

There are a variety of leakage-detecting methods based on radiotracers, and choosing the method depends on the character of the suspected leak. The most frequently used methods with their applicability are listed below:

- In the case of a very large leak through a valve the leakage flow rate can be determined using standard methods of flow measurement with radiotracers.
- An arrangement where the flow entering a reactor is preheated in a heat exchanger by the flow leaving the reactor is quite common, for example, in the oil refinery industry. A leak in the heat exchanger can be detected by residence-time measurement. A tracer pulse is injected into the flow and the tracer concentration of the output flow is monitored. Any leakage is detected as a subsidiary peak preceding the main peak in the residence-time distribution. The amount of leaked material and the location of the leak can be estimated from this measurement.
- The direct tracer technique for leakage detection includes injection of tracer into a system and monitoring the system environment where the leak is suspected. The monitoring can be done either by using detectors *in situ* or by sampling. Sampling is preferable in the case of small leaks since the measuring of

samples can be done very accurately by increasing the analysis times. Moreover, the background can be eliminated.

- Leakage detection for pipes and long pipelines can be done by filling the pipe with a tracer and then leaving it under pressure in order for some of the tracer to leak out of the pipe. After the pipe is flushed out, the leak can be sought using a radiation monitor. In the case of underground pipes of depth more than  $\sim 0.5\text{--}1\text{ m}$ , a special pig can be used to localize the leaked tracer or the radiation monitoring can be done from strategically placed boreholes.

### Determination of Mass and Volume

Tracer methods are of practical interest when very large volumes of arbitrary shape are determined or a very small fraction of a large amount of material is mixed with a known amount of another material. If a small volume of tracer  $V_t$  is mixed evenly with a large volume  $V$ , and the count rates of the samples are  $c_t$  and  $c_0$  in constant geometry for the tracer and bulk material, respectively, and the count rate of the solution is  $c_s$ , then

$$c_0 V + c_t V_t = c_s (V + V_t) \quad [7]$$

This can be solved either for  $V$  or  $V_t$ ,

$$V = \frac{c_t - c_s}{c_s - c_0} V_t \quad [8]$$

and

$$V_t = \frac{c_s - c_0}{c_t - c_s} V \quad [9]$$

The first equation is for the isotope dilution method and the second for the reverse isotope dilution method.

### Wear Studies

The principle of isotopic wear studies is to label the material to be worn and monitor the material loss by radiation measurement. A typical example is studying car engine piston rings labeled, e.g., by neutron activation and measuring the accumulation of radioactivity in the lubricant oil. The measured count rates can be converted to mass by the appropriate calibration. Another example from the vehicle industry is to study the wearing of car tyres.

### Measuring Mixture Homogeneity

The determination of mixture homogeneity is based on labeling one component and taking samples from the mixture in order to determine the variations in tracer concentration.

As a measure for the mixture homogeneity the relative standard deviation of the measured count rates can be used. It is important to subtract the variations due to the statistical nature of radioactive decay, which would otherwise contribute to the measured variance. It has to be noted that the determination of homogeneity is not unambiguous. The variations in tracer concentration of samples depend on the sample size and on the microstructure of the material.

It is possible to measure the homogeneity of a ready-mixed composition by taking several samples from different positions. Another possibility is to monitor the variations in the tracer concentration during mixing. The maximum degree of mixing is achieved when the variations cease decreasing.

An online measurement of a continuous mixer can be made by injecting tracer continuously into the material to be mixed with the bulk material and measuring count rates after mixing. The sample size is now determined by the measurement geometry and the measuring time. The axial homogeneity can be determined as a variation of the measured count rates. If two opposed detectors are used, it is possible to obtain information about radial mixing as the difference in the response between the two detectors.

### Use in Physical and Chemical Research

The basic principles used in research work are similar to those used in industrial tracer applications.

Physical applications are mainly concerned with mass transfer. Typical applications are the study of separation processes, e.g., determining the efficiency of a filter.

Very slow diffusion and self-diffusion processes in solids can be determined using radiotracers. Two methods are used. In one, a thin surface containing tracer is applied to the sample. After some time has elapsed, the sample is sliced parallel to the surface and the radioactivity of each slice is measured. Another method is to use an  $\alpha$ - or  $\beta$ -active tracer. As the tracer diffuses into the sample, a direct measurement of the surface radioactivity gives information about the diffusion process.

Adsorption of a gas on a solid surface may be of interest, e.g., when studying the efficiency of a catalyst. The adsorption measurement can be made using a labeled gas and measuring the surface activity. The background radiation due to the gas between the detector and the studied surface can be eliminated with a measurement in similar geometry without the adsorbent.

Chemical analysis can use tracer techniques to study reaction mechanisms and kinetics. Reaction pathways can be determined by labeling the starting

substance. When this is allowed to react in a solution containing an assumed intermediate, the intermediate character is verified if the intermediate contains tracer after the reaction. Reaction pathway studies can be more accurate if chemical methods are used to determine the position of the label. This involves the use of sophisticated processes, in which the labeled molecule is graded in successive reactions and the radioactivity of the intermediates are monitored.

Isotopic exchange is the best example of the power of radiotracer techniques in chemical research. Isotopic exchange reactions have no inactive analogies. A system with two states of an element in equilibrium apart from isotopic distribution can be studied:

Information on the character and strength of chemical bonds as well as the mechanism of the reactions accompanying the exchange can be obtained.

There are numerous isotopes that are used in physical and chemical research. To mention but a few elements that have radioactive isotopes with both relatively short and long half-lives, such as Na, Zn, Kr, Ag, Sn, Sb, I, and Hg. The most used isotopes to study reaction mechanisms and reaction kinetics are probably  $^{14}\text{C}$  and tritium,  $^3\text{H}$ , because they are both used in organic chemistry; tritium also has inorganic applications.

### Age Determination

Radioisotopic age determination is used for industrial purposes if a material is susceptible to aging. A method called double isotopic labeling can be used. The product is labeled when manufactured with a pair of isotopes having different half-lives and radiation energies. Examples of suitable pairs are chlorine-36 and manganese-54, chlorine-36 and niobium-95, and technetium-99 and niobium-95. As time passes, the initial ratio of the isotopes is changed.

Geological research can make use of radioisotopes in determining ages of minerals. This has been described in detail in another article.

## Radiotracers in Clinical Work

Tracers in clinical work are used in diagnostics and therapy as well as in pharmacokinetic and metabolic studies. The first clinical tracer tests were made in the 1920s in order to measure blood flow rate. Radon gas dissolved in salt solution was used as the tracer. Nowadays the clinical use of radiotracers covers diagnostic use, radiotracers are used as a tool in drug

design, and some forms of radiation therapy take advantage of radiotracers.

A variety of radiotracers are used in clinical work, the most used isotopes being technetium-99m, iodine-131, tantalum-201, xenon-133, and indium-113m. The use of technetium,  $^{99\text{m}}\text{Tc}$ , dominates, since it can be made to react with many substances having specific biological behavior.  $^{99\text{m}}\text{Tc}$  is obtained from an isotope generator, which is based on the radioactive decay of radioactive molybdenum,  $^{99}\text{Mo}$ . Pharmaceuticals containing  $^{99\text{m}}\text{Tc}$  are usually introduced by intravenous injection. Some radiopharmaceuticals may also be introduced orally, e.g., for those containing iodine this is the common procedure.

### Diagnostic Use of Tracers

**Radioimmunoassay (RIA)** This is widely used to measure hundreds of substances of biological interest. The principle of classical RIA is to obtain the unknown concentration of the unlabeled antigen by comparing its inhibitory effect on the binding of radiolabeled antigen to a specific antibody with the inhibitory effect of known standards. The principle of RIA closely resembles the isotope dilution method.

In classical RIA, there is less binding protein, the antibody, present than there is antigen. At the end of the reaction period there are present a bound fraction and free fraction, both containing labeled antigen. The amount of labeled antigen in the bound fraction, however, decreases as the overall amount of unlabeled antigen increases and, thus, the ratio of radioactivity between the bound and free fractions can be used to determine the unknown amount of the unlabeled antigen. The technique for separation of antibody-bound antigen from free antigen is critical for the method. Nowadays the concept of RIA also covers the concept of labeled-antibody techniques.

**Nuclear medians imaging techniques** These techniques have an important role in diagnostic work as a tool for detecting and localizing damage, tumors, etc., in tissue and organs. A  $\gamma$ -camera integrated with modern computer technology is a basic tool for data acquisition and processing in nuclear imaging. Technetium ( $^{99\text{m}}\text{Tc}$ ) labeled tracers are used in most imaging applications.  $^{99\text{m}}\text{Tc}$  is easily obtained from an isotope generator and has a favorable half-life and a suitable  $\gamma$ -energy, 140 keV, for detection.

Figures 4 and 5 give examples of gamma camera images. Figure 4 is the image obtained from a normal lung and Figure 5 shows a pulmonary embolism. Intravenously administered particles ( $\approx 20\text{ }\mu\text{m}$ ),  $^{99\text{m}}\text{Tc}$ -macroaggregates, were used for the scintigraphy of the lungs. The particles remain temporarily

**Figure 4** Gamma-camera image of normal lungs. (Reproduced from *Technetium Atlas* (1973) Petten, Holland: Philips-Duphar BV.)

**Figure 5** Pulmonary embolism shown by a gamma-camera. (Reproduced from *Technetium Atlas* (1973) Petten, Holland: Philips-Duphar BV.)

fixed in the arteria pulmonalis until they are cleared away mechanically and by phagocytosis.

Bone imaging is based on increased blood flow and the metabolic activity of new bone formation when bone is damaged by disease or injury. Many technetium-labeled bone seeking agents have been introduced, e.g.,  $^{99m}\text{Tc}$ -methylene diphosphonate ( $^{99m}\text{Tc}$ -MDP), which has a low cost, easy preparation,

high bone extraction rate, and rapid soft tissue clearance.

Radionuclide brain scintigraphy utilizes the accumulation of some tracers relative to healthy brain tissue when the integrity of the so-called blood-brain barrier is disrupted. The most commonly employed tracers are  $^{99m}\text{Tc}$ -pertechnetate ( $^{99m}\text{TcO}_4$ ),  $^{99m}\text{Tc}$ -diethylenetriaminepentaacetic acid ( $^{99m}\text{Tc}$ -DTPA), and  $^{99m}\text{Tc}$ -glucoheptonate ( $^{99m}\text{Tc}$ -GH).

The thyroid gland is an organ often studied with the help of radiotracers. Suitable tracers are the radioactive isotopes of iodine,  $^{123}\text{I}$  and  $^{131}\text{I}$ , as well as  $^{99m}\text{TcO}_4$ . Hyperthyroidism is indicated by enlargement of the thyroid, and hypothyroidism can be detected as a decreased uptake of the tracer. A heterogeneous tracer distribution also indicates an abnormality of the thyroid.

Cardiac scintigraphy can be used to obtain parameters of cardiac perfusion and function.  $^{99m}\text{Tc}$ -pyrophosphate can be used to assess acute myocardial infarction. In the case of myocardial infarction the agent localizes in the area of necrotic tissue, forming an intense spot of radioactivity. Global uptake of activity in the ventricular myocardium usually represents some other cardiac disease.

A cardiac perfusion study is done using tantalum-201 ( $^{201}\text{Ta}$ ) chloride at rest or during both exercise and rest. A defect is noted as the absence of or greatly reduced activity in the area of the myocardium. If the defect is noted during both exercise and rest, the area is considered to be irreversibly scarred and previous myocardial infarction is assumed. If the defect is noticeable only in the rest study, a reversible and often surgically correctable perfusion abnormality is assumed.

The ventricular ejection fraction can be determined using radiotracers. The activity in the ventricle is proportional to the amount of blood. Using a tracer that remains in the blood circulation and a  $\gamma$ -camera with a high-sensitivity collimator, the ejection fraction can be determined.  $^{99m}\text{Tc}$ -labeled red cells provide a suitable tracer for this purpose. The ejection fraction of the left ventricle is normally  $>50\%$  and this is increased during exercise. A decreased ejection fraction of the left ventricle during exercise is evidence of coronary disease. An abnormal ejection fraction of the right ventricle indicates a pulmonary disorder.

The liver and spleen can be studied with  $^{99m}\text{Tc}$ -labeled sulfur colloid. Space-occupying lesions such as cysts, abscesses, hematomas, or tumors can be detected in static images. For hepatobiliary evaluation derivatives of iminodiacetic acid labeled with  $^{99m}\text{Tc}$  are used.

Renal scintigraphy provides a means to assess aberrant renal anatomy and pathophysiology. The renal

cortices can be visualized with  $^{99m}\text{Tc}$ -dimercapto-succinic acid or  $^{99m}\text{Tc}$ -glucoheptanate. Determination of the functional status of a transplanted kidney is an important area of renal scintigraphy.  $^{99m}\text{Tc}$ -DTPA can be used as the tracer to evaluate semiquantitatively flow and function of a transplanted kidney.

PET is used mainly in the study of brain metabolism. The demand of the tracer to be  $\beta^+$ -active restricts the variety of the usable tracers. Isotopes mainly used in PET are carbon-11, nitrogen-13, oxygen-15, and fluorine-18. These are produced by cyclotron and have quite short half-lives (20.4, 10.0, 2.1, and 110 min, respectively).

### Use in Drug Design

Tracer methods provide a tool in different stages of drug development. In the design stage a few atoms in a drug can be replaced by radioactive ones, and the labeled drug allowed to react with cells or animal tissues. The autoradiograph reveals the binding sites as drug accumulation in a certain active site, a receptor. Thus, clues about the reaction mechanism between the drug and the biochemical target are obtained. New drugs developed are submitted to very strict safety tests. Pharmacokinetic and metabolic studies are used in this stage of drug development.

Thoroughly planned preparation and chemical purity of the radiolabeled drug are of essential importance for the success of pharmacokinetic and metabolic studies. It is desirable that the label site in the drug molecule is not lost through any probable metabolic mechanism. In cases, in which the drug is divided into two major entities, it may become necessary to label both portions.

Prior to human studies, tests of the radioactive drug are made with laboratory animals. Observations with animals include monitoring radioactivity in blood samples and monitoring accumulation of radioactivity in urine and fecal samples. Metabolic pathways are determined and possible organs or sites of drug retention are determined.

Human studies with a radiolabeled drug must be clearly justified on the basis of animal studies and analytical results obtained with the unlabeled drug. If there is any tendency for the drug to accumulate in some organs, it places such experiments in doubt. The main purpose of the human test made with a radiolabeled drug is to evaluate the complete material balance for the drug intake and output to ensure that no unknown metabolic pathway exists.

### Use in Radiation Therapy

Radiation therapy is based on the fact that infected cells or cancer cells usually have a poor resistance to

the harmful effects of radiation, while ordinary healthy cells have comparatively good resistance to radiation and are renewable.

One form of radiation therapy is isotope therapy, in which a labeled substance that is known to accumulate in the defective organ is introduced into the body. The radiopharmaceutical may be a compound labeled with radioactivity or a radioactive isotope that has the tendency to accumulate. The most-used application of isotope therapy is the use of radioactive iodine  $^{131}\text{I}$  to treat hyperthyroidism and cancer of the thyroid. The rest of the treatments are covered by treatment of blood illnesses with compounds containing radioactive phosphorus  $^{32}\text{P}$  or the treatment of joints with the yttrium isotope  $^{90}\text{Y}$ .

A recent innovation under study in the area of radiation therapy is boron-neutron capture therapy for brain tumor. This form of therapy uses an inactive tracer containing boron, an element with a high absorption rate of neutron radiation. When the radiopharmaceutical has accumulated in the tumor, the patient is exposed to neutron radiation, which is absorbed by boron. The energy of secondary low-range  $\alpha$ -radiation, which is formed in the boron-neutron reactions, is then absorbed by the tumor cells that are to be destroyed.

## Applications in Food and Environmental Analysis

### Food Analysis

Application in nutritional technology often resembles pharmacokinetic studies in clinical work. The aims of such studies can also be considered to be quite similar, i.e., to investigate the fate of food substances in the digestive system and to ensure that no unacceptable effects are present. For example carbon-14 ( $^{14}\text{C}$ ) can be used in studying metabolic effects related to food carbohydrates. Another application of the tracer technique is determining the origin of the food substance, e.g., the species of meat can be identified by RIA.

The principle of isotopic age determination is used in food analysis. Radiocarbon analysis can be used to detect whether a product is of natural or synthetic origin. The absence of  $^{14}\text{C}$  in the sample would indicate a synthetic origin, while the presence of  $^{14}\text{C}$  indicates a natural origin. The determination of tritium contents can be used, e.g., to determine the age of wine.

### Environmental Analysis

Environmental analysis with radiotracers is often related to monitoring industrial activities with

potential environmental impact. Wastewater management is an area where radiotracers are often used. The functioning of large aeration pools and sedimentation tanks is often difficult to predict. However, tracers provide a technique involving the measurement of the residence time distribution for this purpose. Flow measurement techniques using radiotracers can also be used in flow meter calibration and validating in arbitrary-shaped flow channels and for the large flow rates often met in wastewater management.

In agricultural research, radiotracers have been used to study the intake of fertilizers by plants as well as for studying the absorption of fertilizers by the soil. Isotopically labeled compounds have also been used to study the movement and degradation of pesticides.

The final disposal of nuclear waste is a major question in the environmental debate. One scenario for waste disposal is burying waste in bedrock. Radiotracers have been used to determine bedrock properties by the residence time distributions between boreholes. Another source giving information on how nuclear waste would behave in the bedrock is to study natural analogies, e.g., uranium deposits.

Global environmental research includes such items as studies of the hydrological cycle, deforestation, erosion, sedimentation, and climatological studies, as well as investigation of pollutant movements and analysis. Radiotracers can be utilized in all of these interconnected subjects. Global environmental studies are focusing on understanding the mechanism of the world climate and possible man-made changes to it, the 'greenhouse effect' being a major question.

Tritium ( $^3\text{H}$ ) has proved to be useful in studying surface water movements as well as movements in soil and bedrock. Age determination of groundwater and ice can be performed using the ratios of several natural isotopes.

Sedimentation in rivers, a major consequence of deforestation, can be studied by determining the age

of different sediment layers. The isotopes that have been utilized are lead-210, cesium-137, and polonium-210.

Erosion and desertification can be studied, e.g., by determining changes in cesium-137 levels in surface soil, the origin of cesium-137 being the fallout of early nuclear experiments.

Studies of pollutants include the investigation of pollutant movements in water, soil, and the atmosphere. The tracer may be of natural or artificial origin. A widely studied large-scale case is the Chernobyl accident of 1986.

## Introduction

A meaningful definition should reflect the differences between the radio-reagent method and indicator

analysis in addition to setting the boundary with isotope dilution analysis. In indicator analysis (sometimes called the method of labeled atoms; radiotracer methods), an appropriate isotope of the analyte is added before the chemical operations are started. After mixing, it is practically impossible to separate radioactive and inactive ions, molecules and atoms of the same chemical composition, so the amount of substance in every part of the system can be

determined at any time by measurement of the radioactivity. The conditions for the application of this method are that:

1. all the analytes are in reactive form at the start of the analysis; and
2. the proportionality constant does not change during the chemical operations.

The main feature of the 'isotope dilution method' is that complete isolation of the analyte is not necessary. Isotope dilution can be called the method of corrections. Another characteristic of isotope dilution analysis is its use of a change in specific activity.

The 'radio-reagent method' is based on the use of a radioactive species in a quantitative reaction, and measurement of the change in activity of that species in the course of the reaction. The radioactive species may be a labeled reagent, the analyte, or a substance able to give an exchange reaction with some compound of the analyte.

Consequently, characteristic features of this method are as follows:

1. the determination is based on a well-known chemical reaction;
2. the fraction of the labeled substance consumed in the reaction passes into a second phase;
3. this fraction is determined by the decrease, increase, or appearance of radioactivity in the selected phase; and
4. calculation of the concentration of the analyte is based on a knowledge of the corresponding factor relating radioactivity to concentration or mass (grams, grams per liter, moles, moles per liter, etc.).

After separation from excess reagent (by liquid-liquid distribution, chromatography, precipitation, etc.), the mass or concentration of this product is determined from activity measurement. The determination is based on a radioactive substance chemically different from the analyte substance (in contrast to isotope dilution analysis); therefore, the chemical reaction is of prime importance. By variation of this key reaction, the principle can be adapted to various procedures. The superiority of radio-reagent methods over classical separation techniques arises from the use of an inactive carrier and the high sensitivity of the activity measurements, which are not subject to interference by the carrier or other substances.

## Classification

The classification of radio-reagent methods is difficult. Depending on the type of chemical interaction

and relationship of the analyte to the radioactive substance measured, radio-reagent methods can be divided into three basic groups:

1. The radioactive substance is a typical reagent that is able to react with the compound to be determined.
2. The method is based on 'nonequivalent' competition; i.e., the radioactive substance is able to exchange with the analyte.
3. The method is based on 'equivalent' competition; i.e., the labeled substance is chemically identical to the substance to be determined.

The difference between these groups depends on which of the substances involved is radioactive. For example, if the precipitation of barium or radium sulfate is used in a determination, the following variants may occur: (1) the inactive barium is determined by precipitation with an excess of radioactive sulfate (or inactive sulfate is determined by a surplus of radioactive barium); (2) barium is determined by precipitation with an insufficient amount of sulfate in the presence of radium, which acts as an indicator; thus the higher the barium content, the lower the fraction of barium precipitated and, correspondingly, of radium co-precipitated; (3) a constant but insufficient amount of sulfate can be used for the determination of barium, the indicator for the completion of precipitation being radioactive barium.

From a practical viewpoint, it is convenient to divide radio-reagent methods into five groups:

1. Simple radio-reagent methods in which the reactions take place quantitatively, i.e., either the analyte or reagent is completely consumed and compounds of definite composition are formed.
2. Methods of concentration-dependent distribution (CDD) utilizing reactions where products of unstable composition are formed, but in which the extent of reaction is determined by the corresponding equilibrium constant or reaction time.
3. Isotope-exchange method based on the exchange of isotopes between two different compounds of one element, with a radioactive isotope in one of the compounds and a nonradioactive isotope in the other, usually the analyte.
4. Radio-release methods comprising procedures in which the analyte reacts with a radioactive reagent, thus releasing an aliquot of the reagent activity, in most cases into the gas phase.
5. Radiometric titration usually involves use of radioactive reagents to determine the equivalence point (endpoint) but these are variants that do not use a radio-reagent; instead they are based on a

change in the intensity of radiation caused by its absorption or scattering in a medium containing the analyte.

## Simple Radio-Reagent Methods

These methods utilize a reaction with a suitable reagent, and sometimes with a third substance; one of the reagents is radioactive and the reaction is quantitative.

Simple radio-reagent methods can be classified into the following three groups:

1. determination with labeled reagents;
2. determination with labeled analyte; and
3. determination with labeled competing substances.

### Determination with Labeled Reagents

In this most widely used type of simple radio-reagent method, an excess of radioactive reagent solution of known analytical concentration is usually used. However, it is necessary to separate the active product from the excess of radioactive reagent. For this reason, this procedure makes use of various separation techniques, such as precipitation, formation of extractable chelates, or sorption. The majority of determinations are based on classical precipitation reactions.

In these determinations, the substance to be determined ( $n_R$  mol) forms a precipitate, extractable compound, or other separable substance. After the separation of the product, the radioactivity of the product ( $A_P$ ), or the excess of unreacted reagent ( $A_E$ ), or both, are measured. The following relationship is valid:

$$\frac{A_R}{n_R} = \frac{A_P}{zn_x} = \frac{A_E}{n_R - zn_x}$$

from which

$$n_x = \frac{n_RA_P}{zA_R} = \frac{n_R}{z} \left( 1 - \frac{A_E}{A_R} \right)$$

where  $A_R$  is the radioactivity of the reagent and  $z$  denotes the stoichiometric ratio in the compound formed (the number of moles of the reagent interacting with 1 mol of the test substance). In cases where the exact composition of the compound formed is not known, a calibration graph can be used. Quantitative isolation of trace amounts of the reaction products poses another important problem (Table 1).

A portable apparatus has been developed for the determination of chloride in water (0.001%) by precipitation with silver labeled with <sup>110m</sup>Ag. A rapid and routine method for the determination of sulfate in soils is based on its precipitation with barium salt labeled with <sup>133</sup>Ba.

In some cases filtration, sedimentation, or centrifugation can be omitted, for example, when the radioactive precipitant is a gas. <sup>14</sup>CO has been used in this way to determine hemoglobin in blood; and <sup>131</sup>I for the determination of bismuth in the presence of an excess of iodide ions using extraction separation.

### Determination with Labeled Analyte

This type of radio-reagent method is the opposite of determinations using a labeled reagent. Both groups of determinations have a common feature in that the radioactively labeled substance must be present in excess. Should the nonradioactive component be in excess, then the entire added radioactivity, irrespective of the quantity of the components, would be found in the phase of the reaction products and a determination would be impossible.

The radioactive indicator is added to the unknown sample and isotope exchange is allowed to take place; then the reagent is added in a substoichiometric but known quantity. After the reaction is complete, the phases are separated and activities measured. In those cases where the activity of the equilibrium solution is measured, the unknown concentration can be

calculated from the equation:

$$x + x_0 = \frac{A_{\text{init}}B}{A_{\text{init}} - A_{\text{equilib}}}$$

where  $x$  is the quantity of analyte (equivalents),  $x_0$  the amount of added radioactive indicator (equivalents),  $B$  the amount of unlabeled reagent (equivalents), and  $A_{\text{init}}$  and  $A_{\text{equilib}}$  represent the total activity of the initial and equilibrium solutions, respectively.

In this variant of the radio-reagent method, solvent extraction has found greater application.

### Determination with Labeled Competing Substances

Analyte  $M_2$  competes with the radioactively labeled substance  $^*M_1$  in the formation of a precipitated compound with a reagent  $R$

$^*M_1R$  and  $M_2R$  occur in a different phase than either substance  $M_1$  or  $M_2$ . The equilibrium constant of the reaction, as a rule, is  $> 1$  so that a significant exchange takes place. This method is used when the labeling of reagent  $R$  cannot be used or when the reagent and its compound with the analyte are transferred into the same phase. Generally, a relatively soluble precipitate with one radioactively labeled component (e.g.,  $^{45}\text{CaCO}_3$ ) is brought into contact with a solution containing the analyte ( $^{45}\text{Ca}^{2+}$ ) from the precipitate into the solution, and a less soluble precipitate ( $\text{PbCO}_3$ ) is formed. The resulting radioactivity of the solution is proportional to the initial amount of lead.

### Method of Concentration-Dependent Distribution

The method of CDD is based on the utilization of a calibration graph that shows the dependence of the distribution ratio in a two-phase system on the total concentration of the substance to be determined.

Characteristic features of the method of CDD are as follows:

1. The analysis is based on the distribution of a radioactive substance between two phases or between several parts of the systems used (paper chromatography, electrophoresis).
2. The ratio of the activities in both phases and parts of the system depends strongly on the initial concentration of the unknown substance.
3. The distribution is not given by the stoichiometric ratio of the reacting substances; that is, not by total

saturation of one phase or a nearly complete consumption of the reagent, but is given exclusively by the corresponding equilibrium or kinetic constants.

The determination of chloride in water samples by using a radioactive silver chloride ( $\text{AgCl}$ ) precipitate can be taken as an example. A water sample with an unknown concentration of chloride is shaken with an excess of labeled  $\text{AgCl}$  precipitate and the radioactivity of silver is measured in the equilibrium solution. The higher the chloride concentration the lower is the concentration of silver in solution (owing to the constancy of the  $\text{AgCl}$  solubility product). The  $\text{Cl}^-$  ions determined do not react with the  $\text{AgCl}$  precipitate, they only suppress its dissolution. The amount of chloride in the precipitate has no direct relationship to the concentration of  $\text{Cl}^-$  ions in the sample solution.

The second example is the determination of barium based on sorption on a hydrated iron(III) oxide precipitate. It has been found that the distribution coefficient of barium between the precipitate and the solution (under constant experimental conditions such as phase ratio, pH, concentration of other substances, temperature) depends on the total concentration of barium in the system. If this dependence is determined experimentally, it can be used for the construction of a calibration graph and the determination of barium. In this case, a known amount of a suitable barium radionuclide is added to the unknown amount of barium salt, and the adsorption is allowed to take place under standard conditions. From the activities of both phases, and use of the calibration graph, the unknown concentration of barium, corresponding to the measured ratio  $\text{Ba}(\text{precipitate})/\text{Ba}(\text{solution})$ , can be calculated.

In classifying the methods of CDD, it is useful to define two extreme types of determination: 'saturation analysis' and 'nonsaturation analysis'.

In saturation analysis, the cause of the change in the distribution of the radioactive substance is an increase in the saturation of the reagent by the given substance. In the example mentioned above, the hydrated iron(III) oxide adsorbed is successively saturated with barium ions. The term saturation analysis originally appeared in the literature in connection with the determination of biochemically important substances (steroids, hormones, vitamins) and is equivalent to the term radioimmunoassay.

For the determination of metals, reagents forming extractable chelates or ion associates or reagents forming neutral or negatively charged complexes are most often used. The ratio of complexed metal to uncomplexed metal is greater at lower metal concentration at constant reagent concentration under

identical experimental conditions. The degree of complexation can be measured experimentally using liquid–liquid distribution, ion exchange, sorption, or by other means.

In nonsaturation analysis, the cause of the change in the distribution coefficient is the shift of the chemical equilibrium due to an increase in the concentration of the substance to be determined, irrespective of the extent of saturation. The concentration of the analyte may differ from that of the reagent by several orders of magnitude. The determination of some extractants can serve as a typical example. The extraction of microgram quantities of metals depends on the concentration of extractants, and the calibration graph may be used in the form  $\log D$  versus  $\log c_{\text{HA}}$ , where  $D$  is the distribution ratio of the metal in question and  $c_{\text{HA}}$  is the concentration of the reagent.

The number of procedures described that use nonsaturation analysis is limited. These procedures are generally characterized by extremely high theoretical sensitivity but low precision.

## Isotope Exchange Methods

This type of determination is based on the exchange of isotopes between two different compounds of the element X, one of which (XA) is nonradioactive, the other (XB) being labeled with a radioactive isotope. After isotopic equilibrium is reached,

The specific activities of the element X in both compounds are equal:

$$A_1/m = A_2/m_x$$

where  $A_1$  and  $A_2$  are the equilibrium radioactivities of XB and XA, respectively, and  $m_x$  and  $m$  are the amounts of X in XA and XB, respectively. The magnitude of  $m_x$  can be computed from

$$m_x = mA_2/A_1$$

or from the calibration graph of  $m_x = f(A_2/A_1)$ ,  $m_x = f(A_2)$  or  $m_x = f(A_1)$ .

Isotopic exchange can be carried out in either a heterogeneous or a homogeneous system.

'Homogeneous isotope exchange' is usually carried out in organic solvents by extracting the element into the organic phase and adding to the separated extract another complex of the element, which is labeled. After equilibrium is attained, one of the chemical forms is reextracted into aqueous phase, provided that the difference between the magnitudes

of the extraction constants of both complexes is high enough.

The determination of phenylmercury compounds is based on the isotope exchange between phenylmercury chloride in the sample and a standard solution of mercury-203 in  $3 \text{ mol l}^{-1}$  HCl. After reaching isotopic equilibrium for the reaction,

The specific activity of mercury is the same in both forms, and for  $m > 100m_x$  it is practically equal to the original specific activity of the added radiomercury. For this reason, the radioactivity of the separated organomercuric compound is directly proportional to its amount. For the separation of  $\text{C}_6\text{H}_5\text{HgCl}$  from  $\text{HgCl}_4^{2-}$ , liquid–liquid extraction can be used.

Methylmercury and phenylmercury are determined down to  $10 \text{ pg ml}^{-1}$  by liquid–liquid extraction from  $3 \text{ mol l}^{-1}$  aqueous HCl into benzene, and addition of  $\text{K}^{131}\text{I}$  to the separated organic phase. Inactive chloride is completely displaced by  $^{131}\text{I}$ :

The method has been used for the determination of methylmercury species in fish and in drinking water.

In heterogeneous isotope exchange, the aqueous solution containing an unknown amount of the elements to be determined is mixed with a solution of a known amount of a suitable complex of the same element in an organic diluent that does not contain an excess of the free complexing agent. One of the chemical forms of the element is labeled. This technique has been used to assay traces of silver in water by shaking the aqueous solution with a solution of labeled (with  $^{110\text{m}}\text{Ag}$ ) silver dithizonate in carbon tetrachloride.

## Radio-Release Methods

In radio-release methods, the nonradioactive test substance is brought into contact with a radioactive reagent. As a result of an appropriate chemical reaction, a portion of the activity of the radioactive agent is released, i.e., it passes from the solid to the liquid or gas phase, or from the liquid to the gas phase. A characteristic feature of radio-release methods is that the radioactive substance leaves the solid or the liquid phase without any nonradioactive substance replacing it.

The determination is carried out most often using a calibration graph, constructed by plotting the quantity of released radioactivity, or the rate of

release, against the concentration of the analyte. In some cases it is possible to calculate the amount of analyte from the amount of radioactivity released, if the specific activity of the reagent and the stoichiometry of the reaction are known. Radio-release methods in which the radioactive reagent is released into the gas phase require rather more complicated instrumentation than that used in simple radio-reagent methods.

Radio-release methods may be classified according to the type of the radioactive reagent employed, i.e.,

1. radioactive kryptonates;
2. radioactive metals; and
3. radioactive salts and other substances.

### Radioactive Kryptonates

The term radioactive kryptonates is used for substances into which atoms or ions of krypton-85 ( $^{85}\text{Kr}$ ) are incorporated (by diffusion of  $^{85}\text{Kr}$ , by bombardment with accelerated krypton ions, by introduction of  $^{85}\text{Kr}$  during sample preparation, by phase transition, etc.). The choice of technique for  $^{85}\text{Kr}$  introduction depends mainly on the character of the solid to be labeled and the reason for which the labeled solid is prepared.

The basis of the use of radioactive kryptonates in chemical analysis is that during the chemical reaction the crystal lattice of the kryptonated carrier is destroyed, the carrier consumed, and the radioactive krypton released. The determination can be done with a calibration graph or by comparison with a standard.

In ozone determination with the radioactive clathrate hydroquinone kryptonate the following reaction is used:

The logarithm of the activity of the released  $^{85}\text{Kr}$  is linearly proportional to the logarithm of the ozone concentration over a concentration range of  $10^{-10}$ – $10^{-6}$  g of ozone per liter of air.

Sulfur dioxide has also been determined by a method based on the mechanism of double release. In the first stage, sulfur dioxide reacts with sodium chlorate to release chlorine dioxide, which is a strong oxidizing agent. The chlorine dioxide then oxidizes radioactive hydroquinone kryptonate and gaseous  $^{85}\text{Kr}$  is released. The following reactions are involved:

and

(The first equation is an oversimplification, since one molecule of sulfur dioxide releases between four and eight molecules of chlorine dioxide.) Much of the earlier work refers to use of sodium chlorite ( $\text{NaClO}_2$ ) but as the chlorine in this oxidation state is  $\text{Cl(III)}$ , it is difficult to see how it can be oxidized to  $\text{Cl(IV)}$  by  $\text{SO}_2$ .

### Radioactive Metals

Radioactive metals can be used in radio-release methods for the determination of oxidizing agents in aqueous solutions. The decisive factors in the choice of the metal are the following: the metal should not react with water, but should react with oxidizing agents to yield ions that do not form precipitates in aqueous media; the metal should have a radionuclide with suitable nuclear properties. These conditions are met by thallium ( $^{204}\text{Tl}$ ) and silver ( $^{110\text{m}}\text{Ag}$ ).

Dissolved oxygen in seawater, drinking water, and wastewater can be determined using metallic thallium labeled with  $^{204}\text{Tl}$ , which is quantitatively oxidized by oxygen. The laboratory equipment for oxygen determination consists of a glass column filled with labeled metallic thallium, which is connected to a flow-type Geiger-Müller (GM) counter. A block diagram of an analyzer used for oceanographic studies is shown in Figure 1.

The vanadate ion is assayed by acidifying the sample ( $\text{pH} \sim 3$ ) and pouring it through a column containing radioactive metallic  $^{110\text{m}}\text{Ag}$ . The silver ions are released into the solution, where the concentration may be measured by a GM or a scintillation counter. The measurement of dichromate ion concentration in natural waters can be carried out similarly.

**Figure 1** Schematic diagram of an analyzer for oceanographic studies. 1 – input filter, 2 – pump, 3 – thallium column, 4 – coaxial cable to surface, 5 – electronics, 6 – GM counter, 7 – filter, 8 – discharge into sea, 9 – battery and transformer, 10 – control panel.

### Radioactive Salts and Other Radioactive Substances

Sulfur dioxide is determined on the basis of the reaction:

This reaction takes place in an alkaline solution through which air containing sulfur dioxide is bubbled. After completion of the reaction, the solution is acidified and the iodine released is extracted.

Active hydrogen in organic substances may be determined by reaction with lithium aluminum hydride labeled with tritium ( ${}^3\text{H}$ ). The activity of released tritium is measured using a proportional counter.

A number of determination are based on the reaction of a solution of an analyte that can form a soluble complex with a radioactively labeled precipitate. In this way it is possible to determine anions forming soluble complexes (e.g.,  $\text{CN}^-$ ,  $\text{S}_2\text{O}_3^{2-}$ ,  $\text{I}^-$ ,  $\text{F}^-$ ). The principle of the determination is given in the following reactions:

### Radiometric Titration

Radiometric titrations follow the relation between the radioactivity of one component or phase of the solution under analysis and the volume of added titrant. The compound formed during the titration must be easily separable from the excess of unreacted ions. This separation is directly ensured only in the case of precipitation reactions (Figure 2). In other types of reactions, the separation can be accomplished using an additional procedure. The endpoint is determined from the change in the activity of the residual solution or of the other phase.

According to the type of chemical reaction used, methods based on the formation of precipitates and methods based on complex formation can be distinguished (Figure 3). Because of the necessity for handling precipitates, precipitation radiometric titrations are difficult to apply to less than milligram amounts and, therefore, have no special advantages

**Figure 2** Radiometric precipitation titration curves. A – test solution active; B – test solution inactive, titrant active; C – both test solution and titrant active.

**Figure 3** Extraction radiometric direct titration curves. 1 – aqueous phase, 2 – organic phase, A – titration of radioactive test solution with inactive titrant, B – titration of inactive test solution with active titrant, C – titration of active solution with active titrant.

over other volumetric methods. The sensitivity of complexometric titrations is limited by the sensitivity of the determination of the endpoint. However, the use of radiometric detection can substantially increase the sensitivity of this type of determination. For the separation of the product from the initial component, liquid–liquid distribution, ion exchange, electrophoresis, or paper chromatography are most often used.

The application of radiometric titrations has declined over the past three decades. Their main advantage is where classical methods for detection of the endpoint are either impossible or subject to interference from the titration medium.

### Introduction

Radioreceptor assays (RRAs) were introduced as an analytical tool in 1970. With the resurgence of interest in natural products, the development of techniques to generate random novel chemicals and advances in molecular biology, RRAs remain an essential tool for identifying novel substances, demonstrating the specificity of substances for target systems, tracking activities following fractionation of complex mixtures, and predicting the potential side-effects of new pharmaceuticals.

RRAs are (1) cost-effective, (2) offer a high degree of precision, (3) have a sensitivity comparable to other analytical techniques, (4) afford rapid turnaround times, (5) are amenable to evaluating large numbers of samples, and (6) do not require prior information regarding the structure of active compounds. RRAs offer the frequently unique advantage of providing information on the biological activity of new chemicals. The number of RRAs is now in the hundreds and is limited only by the availability of an appropriate ligand and a source of receptor.

This article focuses on the principles that underlie RRAs, the practical considerations of the method, and examples of specific applications.

### Methods and Techniques

#### General

RRAs are based on the specific and saturable binding of a radioligand (L) to a biological receptor or enzyme (R) at equilibrium. By 'specific' it is meant that L interacts with a single R. Saturability implies that at some concentration of L there is no further

increase in the amount of L bound to R since all R are occupied by a molecule of L. At equilibrium, the rate at which any single molecule of L dissociates from a molecule of R is equal to the rate that a molecule of L occupies another R.

These relationships are expressed in general terms by the mass action equation:

where [L] is the concentration of free ligand, [R] is the concentration of receptor, [LR] is the concentration of ligand–receptor complex, and  $k_1$  and  $k_2$  are, respectively, the association and dissociation rate constants of the ligand to the receptor.

Radioligands represent the radioactive forms of endogenous neurotransmitters, neuromodulators, hormones or enzyme substrates, or synthetic compounds that interact with the binding sites on receptors or enzymes. Ligands are made radioactive using a number of isotopes (e.g.,  $^3\text{H}$ ,  $^{125}\text{I}$ ,  $^{35}\text{S}$ ,  $^{32}\text{P}$ , or  $^{14}\text{C}$ ) but in practice the most common method involves tritiation or iodination. To be useful a radioligand must have high affinity for the receptor or enzyme, be specific for the receptor, be easy to synthesize, and, most importantly, have similar biological, pharmacological, and functional properties as the parent compound. With few exceptions, ligands are currently obtained from commercial operations that specialize in the production of these materials.

For economic and environmental reasons, there is an emphasis on the development of nonradioactive ligands for use in RRAs. Emerging technologies rely on the substitution of a fluorescent moiety incorporated into the parent compound to track the binding of L to R. It is likely and desirable that these technologies will replace existing methods.

Historically, the source of receptors for use in RRAs has been animal tissues but the techniques of molecular biology are proving an increasingly important source of receptors or enzymes that are

### Introduction

Radioreceptor assays (RRAs) were introduced as an analytical tool in 1970. With the resurgence of interest in natural products, the development of techniques to generate random novel chemicals and advances in molecular biology, RRAs remain an essential tool for identifying novel substances, demonstrating the specificity of substances for target systems, tracking activities following fractionation of complex mixtures, and predicting the potential side-effects of new pharmaceuticals.

RRAs are (1) cost-effective, (2) offer a high degree of precision, (3) have a sensitivity comparable to other analytical techniques, (4) afford rapid turnaround times, (5) are amenable to evaluating large numbers of samples, and (6) do not require prior information regarding the structure of active compounds. RRAs offer the frequently unique advantage of providing information on the biological activity of new chemicals. The number of RRAs is now in the hundreds and is limited only by the availability of an appropriate ligand and a source of receptor.

This article focuses on the principles that underlie RRAs, the practical considerations of the method, and examples of specific applications.

### Methods and Techniques

#### General

RRAs are based on the specific and saturable binding of a radioligand (L) to a biological receptor or enzyme (R) at equilibrium. By 'specific' it is meant that L interacts with a single R. Saturability implies that at some concentration of L there is no further

increase in the amount of L bound to R since all R are occupied by a molecule of L. At equilibrium, the rate at which any single molecule of L dissociates from a molecule of R is equal to the rate that a molecule of L occupies another R.

These relationships are expressed in general terms by the mass action equation:

where [L] is the concentration of free ligand, [R] is the concentration of receptor, [LR] is the concentration of ligand–receptor complex, and  $k_1$  and  $k_2$  are, respectively, the association and dissociation rate constants of the ligand to the receptor.

Radioligands represent the radioactive forms of endogenous neurotransmitters, neuromodulators, hormones or enzyme substrates, or synthetic compounds that interact with the binding sites on receptors or enzymes. Ligands are made radioactive using a number of isotopes (e.g.,  $^3\text{H}$ ,  $^{125}\text{I}$ ,  $^{35}\text{S}$ ,  $^{32}\text{P}$ , or  $^{14}\text{C}$ ) but in practice the most common method involves tritiation or iodination. To be useful a radioligand must have high affinity for the receptor or enzyme, be specific for the receptor, be easy to synthesize, and, most importantly, have similar biological, pharmacological, and functional properties as the parent compound. With few exceptions, ligands are currently obtained from commercial operations that specialize in the production of these materials.

For economic and environmental reasons, there is an emphasis on the development of nonradioactive ligands for use in RRAs. Emerging technologies rely on the substitution of a fluorescent moiety incorporated into the parent compound to track the binding of L to R. It is likely and desirable that these technologies will replace existing methods.

Historically, the source of receptors for use in RRAs has been animal tissues but the techniques of molecular biology are proving an increasingly important source of receptors or enzymes that are

transiently or stably expressed. Cloned receptors offer the advantages of decreased reliance on animals, a high degree of receptor or enzyme expression, and homogeneity of receptor source. Disadvantages include a lack of knowledge of receptors (e.g., glycosylation patterns) cloned in prokaryote systems, leaving open the possibility that the clone has pharmacological characteristics different from the native receptor. Where receptors are composed of multiple, heterogeneous subunits (e.g., amino acid receptors), it is unwise to use cloned material until a better understanding of native receptor subunit composition is available.

## Binding Reactions: Theoretical and Practical Considerations

### Mathematics

The mathematics of ligand–receptor interactions are beyond the scope of the current article. Therefore, only important summary equations describing the bimolecular interaction of L with a single class of receptor are given below. These equations are analogous to the fundamental description of enzyme–substrate interactions first proposed by Michaelis and Menten, with the exception that L replaces the term for substrate, R replaces the enzyme, and LR substitutes for the enzyme–substrate complex. In binding reactions there is no term for product, since the binding of L to R does not result in the alteration of L.

Rearrangement and substitution of eqn [1] produces two summary statements important to the understanding of ligand–receptor interactions. These are respectively,

$$K_d = ([L][R]/[LR]) = k_2/k_1 \quad [2]$$

where  $K_d$  is the equilibrium dissociation constant for the reaction, and

$$[LR] = [L][R + LR]/K_d + [L] \quad [3]$$

Equation [3] is the general form of equation for rectangular hyperbola and a plot of [LR] versus [L] yields a curve with a horizontal asymptote of  $[R_{\text{total}}]$ . By definition, the  $K_d$  of the reaction is  $[R_{\text{total}}]/2$  and is the concentration of L necessary to half-maximally occupy the total receptor population.

Important to the interpretation of RRA data are the events occurring when fixed L and R are incubated in the presence of increasing concentrations of an unlabeled material (I) that prevents the binding of L to R. Experiments are generally referred to as ‘competition’ or ‘displacement’ protocols and

assume the general form shown in eqn [4]:

where [L], [R], and [LR] retain their former meaning, [I] represents the concentration of an unlabeled compound that binds to R, and [IR] is the concentration of the inhibitor–receptor complex. The term  $K_I$  is a constant representing the potency of I to bind to R.

Incubation of a fixed amount of L in the presence of increasing [I] leads to a progressive diminution of the amount of L bound to R. In practical terms, a decreasing amount of radioactivity is measured in the presence of successively higher amounts of I. Competition curves yield sigmoidal plots (Figure 1A) and data of this type are most often expressed by plotting the percentage of L specifically bound to R at each concentration of I. The two important equations derived from this interaction are the Cheng–Prusoff equation and a derivation of the pseudo-Hill plot. The Cheng–Prusoff equation is given by eqn [5]:

$$K_I = IC_{50}/(1 + [L]/K_d) \quad [5]$$

where  $IC_{50}$  is the concentration of I required to inhibit the binding of L to R by 50%.

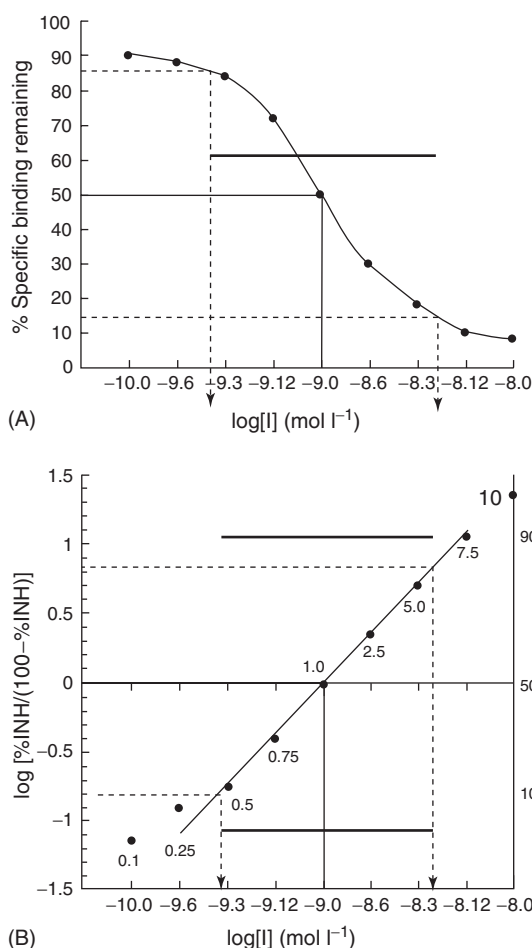

Equation [6] is a derivation of the pseudo-Hill plot:

$$\log \%INH/100 - \%INH = n \log \%INH + n \log IC_{50} \quad [6]$$

where %INH is the amount of inhibition of specifically bound L observed in the presence of a single concentration of I and  $n$  is a slope factor. Using this transformation, the data in Figure 1A have been replotted in Figure 1B and form the basis for quantitative measures in RRAs. These data are conveniently generated manually using log–logit paper or through the use of appropriate software.

### Selection of Ligand

There are a variety of ligands available to label biologically important receptors or enzymes (see Table 1). Many of these are highly specific for receptor subtypes, whereas others label a heterogeneous family of receptors. The choice of ligand will depend on the goals of the experiment. For example, it would be appropriate to select the generic ligand, [ $^3H$ ]naloxone, which labels all biologically relevant opiate receptors, if one were interested only in determining if a natural product extract contained

**Figure 1** Graphical representation of receptor binding data. (A) The curve is the standard representation of data resulting from experiments described by eqn [4]. Typically, fixed concentrations of L and R are incubated in the presence of increasing concentrations of an inhibitor, I, which competes for with the binding of L to R. As the concentration of I is increased, there is a progressive decrease in the amount of L bound to R. Dashed lines (and the bar at top) show the useful range of the assay; the bold line shows the concentration of I required to inhibit binding by 50%. (B) The data in (A) have been transformed using log-logit methods to yield a linear format useful for RRAs. Values associated with the line represent the absolute amount of I present in the assay assuming the concentrations shown and a final assay volume of 1 ml. Other notations are identical to those in (A).

opiates. On the other hand, if the object of the study were to identify selective  $\mu$  opiate antagonists, [<sup>3</sup>H]Tyr-D-Ala-Gly-NMe-Phe-Gly-ol (DAGO) would be more appropriate since this interacts with the desired receptor subtype. In every instance, however, ligands should label only a single family of receptors or enzymes.

### Linearity

Linearity is a correlate of receptor saturability. Intuitively, one would predict that as the concentration of

R added to incubations is increased, the amount of L specifically bound to the receptor would correspondingly increase as a linear function of [R]. Over a certain range of [R] linearity appears to be the case; beyond these limits, specific binding of L to R becomes nonlinear. In a manner analogous to enzyme reactions this occurs as a result of ligand availability becoming a driving force of the reaction. The interaction of L with R becomes 'substrate-dependent' and curves deviate from linearity.

For practical reasons it is important to determine the range of [R], which may be added to the RRA and still maintain linearity. Increasing [R] increases the amount of radioactivity measured in each incubation but can be a mistake since assays no longer adhere to the fundamental assumptions of ligand-receptor interactions.

### Equilibrium

Because binding assays follow mass action kinetics, a finite period of time is required for the reaction to reach equilibrium, the point at which the rate of association of L with R equals the rate of dissociation of the LR complex. To be a useful tool, RRA must always be performed under equilibrium conditions.

In an ideal world, it would be expected to be possible to predict the time required to reach equilibrium based on a knowledge of the affinity of R for L and the temperature at which the reactions are performed. Unfortunately, this is not the case and the time required to achieve equilibrium conditions must be determined in each laboratory for each assay. This is easily done by performing association experiments that determine the amount of L specifically bound to R as a function of time. In practice, most assays reach equilibrium within 1–2 h.

### Pharmacology

Beyond the characteristics described above (linearity, equilibrium conditions, saturability) an RRA must be specific. That is, the method must measure only those compounds or endogenous substances that are known to inhibit the receptor-ligand reaction in a competitive manner. By competitive it is implied that substances inhibit the binding of L to R in a concentration-dependent manner by binding to the same site on R that would otherwise be occupied by L.

In developing an RRA, the specificity of the system is shown by demonstrating that reference agents, known to interact with R, inhibit the binding of L. With the increasing reliance on cloned and expressed receptor systems, this latter step is crucial since expression of receptors in bacterial or mammalian

cell-based systems may lead to differences in the pharmacological specificity of the clone.

Final validation requires the demonstration that RRAs provide similar or identical quantitative data to those generated using other analytical methods. The latter is particularly important when using RRAs to measure substances endogenous to biological samples.

## Practical Aspects of RRA

### Equipment

The equipment necessary to perform RRAs is generally available to any laboratory engaged in biomedical research. Common items include the obvious (balances, pH meters, tissue homogenizers, refrigerators/freezers, etc.) and most assays require a high-speed centrifuge capable of generating 50 000g. Because RRAs remain based on the use of radiolabeled ligands this necessitates access to  $\beta$ - and  $\gamma$ -counters. Access to animals and animal housing facilities are needed, although if cloned and expressed receptors represent the tissue source, tissue culture facilities must be available. Due to the resurgence of the popularity of RRAs, several commercial operations now offer stable freeze-dried receptor preparations for use.

Due to the availability of high-affinity ligands for many receptors, reactions are often terminated using vacuum filtration. In this procedure, the ligand that is not bound to the receptor is separated from the receptor–ligand complex by trapping the complex on a filter support. Commercial units are available for this purpose with the most popular capable of terminating 48 individual reactions simultaneously and in less than 1 min.

### Tissue Preparation

The identification of a tissue containing the receptor of interest or the transient or stable cloning and expression in cells is the first step in developing a reliable RRA. While the brain–spinal cord axis represents a major source of receptors, assays based on receptors specific to tissues including gut, platelets, lymphocytes, skeletal muscle, and endocrine organs are well known. Transformed cells are also useful as the point of departure to gather receptors; these may be obtained from public sources such as the American Type Culture Collection (Rockville, MD, USA). Cloned and expressed receptors may be obtained on an individual basis as needed.

Realization of a final receptor preparation depends on the starting material and the specific RRA. In general, preparative procedures are designed to concentrate receptors in a crude manner and remove endogenous substances interfering with the

sensitivity of the assay. Frequently, preparation involves homogenization of tissue(s) followed by low-speed differential centrifugation to remove cellular debris. Higher-speed centrifugation is performed to concentrate membrane fractions rich in the relevant receptor. The final material is ‘washed’ on several occasions using sequential resuspension and centrifugation in large amounts of buffers or water in order to remove endogenous substances that may interfere with the assay.

As a cautionary note, very few assays require tissue(s) obtained from human or potentially pathogenic animal sources (e.g., sheep brain). In these instances, equipment should be dedicated to tissue preparation, appropriate precautions should be taken during the preparation procedure, and equipment should be disinfected after use.

Cloned receptors offer the advantages of high expression, homogeneity, control of pathogenic factors, and the potential to eliminate endogenous substances that may interfere with assay sensitivity. When possible, the use of cloned receptors is desirable.

In some instances it is possible to prepare tissue in batches and store the preparation frozen for future use. This will vary for each assay and some receptors are unstable to freezing mandating the preparation of tissue on the day of assay.

### Sample Preparation

Preparation of samples for use in RRAs varies. If the substance of interest is in biological fluids (e.g., urine, spinal fluid, plasma) it may be possible to add fluid directly to the RRA. In many instances, however, components (salts, proteins) interfere with assay integrity. In this case, it is necessary to devise a preparation scheme suitable for use with the RRA and which does not alter the quantities of the substance of interest, or to incorporate an appropriate internal standard in the method (e.g., radioactive tracer amounts of the compound of interest preferably labeled with an isotope different from that incorporated in the ligand). In the case of natural product analysis, standard aqueous or organic extraction procedures are followed and the sample is freeze-dried or dried to provide the final preparation. Aqueous fractions can be redissolved in assay buffers whereas dimethylsulfoxide (DMSO) is a useful solvent for organic extracts since many RRAs tolerate  $\leq 1\%$  DMSO in the final assay.

### Assay Procedures

The elegance of the RRA is its simplicity, sensitivity, precision, high volume, and rapid turnaround time. In a typical day, as many as 150 samples may be

evaluated in any single procedure. Data are of the type shown in **Figures 1A** and **1B** are usually available the following day.

For assay, tissue preparations containing the receptor of interest are resuspended in buffer and an aliquot is added to tubes containing the radioligand and a sample containing the substance to be measured. In some tubes, solutions containing various concentrations of a reference agent are substituted for the sample. If the substance being measured is known (e.g., a drug or neurotransmitter), it is best to use the same compound to generate the reference curve in order to provide absolute values in the final analysis. When the identity of the substance of interest is not known (e.g., natural products) any appropriate reference substance may be used to generate standard curves and the final data are expressed in arbitrary units relative to the curve, or in terms of the amount of sample (e.g.,  $\mu\text{l}$  or  $\mu\text{g ml}^{-1}$ ) added to the assay.

Final assay volumes are 0.5–1.0 ml. Incubations are generally performed using triplicate tubes, each of which contains identical amounts of ligand, tissue, sample, or reference agent. In the case of sample tubes, it is useful to include at least two, and better yet, three different amounts of sample in triplicate in order to ensure the final result falls in the range of the reference curve.

Following an incubation at the time and temperature appropriate to each assay, reactions are terminated in order to separate L not bound to the R. This is done using one of two methods, centrifugation or filtration. In the former, the incubation mixtures are centrifuged at high speed (e.g., 50 000g; 10 min) to pellet the tissue. The incubation solution is decanted and the pellet is washed rapidly with 5–10 ml of ice-cold assay buffer. The pellet is dissolved in tissue solubilizers, scintillant is added, and the radioactivity contained in the pellet is counted using scintillation spectrophotometry.

In filtration assays, L is separated from the receptor–ligand complex by rapidly filtering the incubation mixtures through an appropriate support. Most assays call for the use of glass fiber filters. The filters are rapidly rinsed with 5–10 ml of ice-cold assay buffer, placed in counting tubes and radioactivity is quantified as described above.

From a practical perspective, filtration assays are generally preferred over centrifugation methods. Equipment is commercially available to filter simultaneously up to 48 samples in under a minute, making it possible to process 300–400 assay tubes in a single day. Assays can be performed in small volumes, reducing costs while substantially increasing assay sensitivity. Finally, emerging technologies

include the development of filter supports presoaked with scintillant, which allow direct assay of filters in the absence of scintillation fluor. When centrifugation assays must be used, commercial equipment and supplies make it possible to perform the entire assay in centrifugation tubes that double as scintillation vials.

### Cautionary Notes

As with any technique, RRAs are subject to limitations and cautions. Assays involving samples obtained from human tissues must be presumed to contain pathogens unless these have been specifically excluded by appropriate testing. In the absence of the latter, equipment used in the assay must be properly disinfected after each use and only individuals trained in correct safety methods should perform the tests.

At the practical level, it should be borne in mind that RRAs can be subject to a number of confounding factors. Chief among these is the possibility that substances contained in samples may interfere with assay specificity. Samples processed with acids or bases, if not properly neutralized, may yield false-positive data since RRAs are pH dependent. It would be ill advised to add organic extracts directly to an RRA since assays are performed in aqueous buffers that are not miscible with all organic solvents.

Receptor preparations often contain enzymes (proteases, esterases, etc.) that degrade compounds of interest. Assays designed to detect peptides or esters should include peptidase or esterase inhibitors and bovine serum albumin to minimize enzyme activity. Whenever enzyme inhibitors are added to assays, the effect of these additions on the characteristics of the assay must be determined to ensure that these additions do not inhibit (or enhance) ligand binding. Where interference is encountered, this is controlled by the addition of the interfering substance to all control incubations as well as in generating the reference curve.

At the practical level, there is always an urge to maximize the signal obtained in the final data output. For RRAs, this means maximizing the amount of radioactivity detected. As intuitively expected radioactivity can be increased by increasing [R], or by increasing [L] (or both) added to assay tubes. The detrimental effects of increasing [R] beyond certain limits have been described above. Increasing [L], while perhaps increasing assay precision, results in a decrease in the sensitivity of the method.

Consideration of the Cheng–Prusoff equation (eqn [5]) provides the rationale. Since  $K_d$  and  $K_1$

are constants,  $[L]$  determines the amount of  $I$  that must be present to achieve an  $IC_{50}$ . When  $[L]$  is increased the ratio  $[L]/[k_d]$  increases and the amount of  $I$  required to inhibit binding is increased. It is always desirable to use the least amount of  $L$  that provides reliable data and an acceptable error limit. A general rule of thumb is to maintain  $L$  at a concentration  $\ll$  (10-fold) the  $K_d$  of  $L$  for  $R$ .

Data analysis begins with the determination of the amount of  $L$  specifically bound to  $R$ . This is the difference between the total and nonspecific binding. The nonspecific binding is then subtracted and for each concentration of  $I$  or sample, the specifically bound decompositions per minute (dpm) are divided by the value for the total specific binding of  $L$ . This result is multiplied by 100 to yield the per cent inhibition of total binding at each concentration of  $I$  or sample.

As shown in **Figure 1A**, these data are plotted on semilog paper to yield the sigmoidal curve characteristic of binding reactions. To simplify data analysis, a linear transformation as shown in **Figure 1B** is useful. Alternatively, the log concentration of  $I$  can be directly plotted against the per cent inhibition using log-logit paper (or appropriate software packages).

As a final step, it is necessary to determine the amount of inhibitor present in experimental samples. This is accomplished by comparing the per cent inhibition of the specific binding of  $L$  caused by each sample to the reference curve and extrapolation to the  $x$ -axis of **Figure 1B**.

If the identity of the substance of interest is known, extrapolation to the  $x$ -axis yields the precise concentration of substance in the sample. As shown in **Figure 1B**, the amount of reference agent added to each tube of the standard curve can be expressed as either a concentration or an absolute amount. If the identity of the substance is unknown, as may be the case when screening for novel chemicals in natural product extracts, an arbitrary value is assigned to describe compound activity.

Like other analytical techniques, RRAs are associated with a degree of variability and it is not uncommon for results to differ by 10–15% among assays. Although sound opinion exists to the contrary, it is recommended that samples producing  $<15\%$  inhibition or  $>85\%$  inhibition of the specific binding be excluded from data analysis, or re-examined on a second occasion. In log-logit analysis, an infinite error is associated with samples producing  $>90\%$  or  $<10\%$  inhibition of binding if the assay has a day-to-day variance of 10%.

To be useful, an RRA must be sensitive and precise. That is, the assay must be capable of accurately detecting minute amounts of important substances in samples. The affinity ( $K_d$ ) of  $L$  for  $R$  is important since high-affinity ligands, in general, produce more robust assays. In practice, however, ultrahigh-affinity ligands present the investigator with technical difficulties. The mathematics of binding assume that the concentration of  $L$  added to the reaction equals the concentration of labeled  $L$  at equilibrium ( $>95\%$  of added  $L$  remains unbound to  $R$ ), and that the concentration of  $R$  is much less than the  $K_d$  of  $L$  for  $R$ . As the affinity of  $L$  decreases more  $L$  is bound to  $R$  at the same time that  $R$  is decreased. This combination of factors results in a progressive diminution of radioactivity measured in the final output. As measured radioactivity decreases, the error increases, resulting in a decrease in the precision of the RRA. For these reasons, the choice of ligand for an RRA must balance the goals of the experiment, the sensitivity which is required, and the practical challenges of assay precision.

The sensitivity of RRAs is optimized by decreasing assay volume or the selection of an  $L$  for which the  $IC_{50}$  of  $I$  of interest competing with the binding of  $L$  to  $R$  is decreased (made smaller). The effects of the latter are evident from consideration of eqn [4].

The sensitivity of RRAs can also be increased by minimizing the final assay volume. When  $[L]$  and  $[R]$  are decreased in a linear fashion relative to assay volume, the final amount (not concentration) of experimental samples  $f$  required to achieve an  $IC_{50}$  is decreased in parallel.

## Gamma-Ray Spectrometry

### Introduction

Presently, gamma-ray spectrometry is the most powerful tool in the field of radionuclide analysis. It is used for the qualitative and quantitative determination of radionuclides that emit gamma radiation. Most of the radionuclides send out gamma radiation during their transformations to stable decay products.

Most nuclear reactions are accompanied by the emission of gamma radiation and therefore this tool is used to observe such reactions or to analyze reaction products.

A gamma-ray spectrometer system consists of a detector, an electronic circuit for pulse handling, and a facility for data storage, data processing, and data display.

The detector is a tool that provides electric signals (pulses). These signals depend on the energy (wavelength) and the number of the gamma photons to be detected. The detector is connected to a system that handles these pulses. The pulse-handling system is an electronic circuit that shapes the pulses, counts them, and classifies them according to their pulse height. Thus, the electronic signals are converted to a pulse spectrum. This pulse spectrum represents the number and the distribution of the energy of the gamma photons. The spectrum is stored in a memory system and can be processed further by the use of appropriate computer programs. The results are shown as a graphical or numerical display.

The advantages of gamma-ray spectrometry are:

- Sample preparation for the analysis is extremely simple and in most cases a radiochemical separation procedure for analysis is not necessary.
- It is very useful for environmental radioassay and for the analysis of low amounts of radioactive materials.
- The data obtained by the detection system are extremely suitable for data processing by a computer and therefore appropriate for the design of automatic analysis systems.
- Gamma-ray spectroscopic devices, although being rather expensive, are available in the market with very high standards of performance and quality assurance.

The interpretation of gamma spectra is sometimes difficult due to the interaction of gamma radiation

with the detector material, wherein additional gamma peaks appear in the spectrum. Therefore, some knowledge of the interactions of gamma radiation with matter is essential to understand the complex structure of the gamma spectra.

### Emission of Gamma Radiation

After an alpha or beta decay, the atomic nucleus is frequently in the so-called excited state, which means that the atomic nucleus still contains lots of excess energy. The transition from a higher to a lower energy state results in the dissipation of electromagnetic radiation of a very short wavelength of gamma radiation. The excited atomic nucleus either falls directly in one step to the ground state or descends in several steps to lower energy states and finally to the ground state. The energy dissipation is characteristic for the radionuclide under consideration and its spectrometric determination can be used for qualitative and quantitative analyses of radionuclides (see **Figure 1**). Gamma-ray spectrometry, therefore, is a specific and powerful tool for the analysis of gamma-emitting radionuclides.

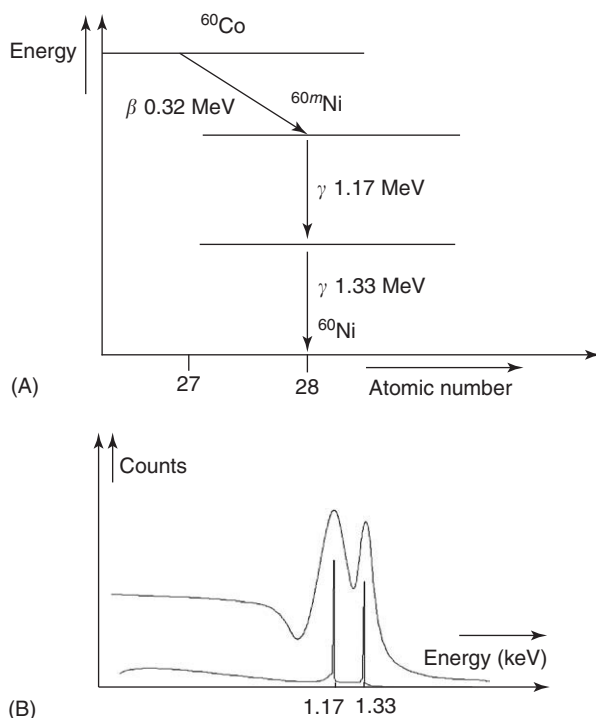

### Decay Schemes

The decay scheme of a radionuclide provides very useful information for its gamma-ray spectrometric determination.

**Figure 1** Gamma spectrum of a soil sample. Natural radionuclides from the uranium and thorium series are detected. The characteristic gamma line of cesium-137 at 662 keV is also displayed. The cesium-137 is due to the nuclear weapons tests and the Chernobyl reactor accident. The sample was taken at Vienna (Austria).

**Figure 2A** shows the decay scheme of cobalt-60, a radionuclide that is frequently used as a radiation source in industrial nuclear applications. Because of the unstable configuration of the atomic nucleus of cobalt-60, a neutron is changed to a proton and nickel-60 is obtained. This nuclear transformation, the change of a neutron to a proton, is accompanied by the emission of a particle with negative electric charge, namely an electron (a beta particle). The new nucleus of nickel shows already a stable configuration considering the amount of protons and neutrons but it contains lots of excess energy that will be dissipated by the emission of electromagnetic radiation due to gamma radiation. The excited nickel nucleus descends in two steps to the ground state. In the first step a gamma radiation of 1.17 MeV ( $1 \text{ MeV} = 1000 \text{ keV} = 1.602 \times 10^{-13} \text{ J}$ ) and in the next step a radiation of 1.33 MeV is released. Therefore, a gamma spectrum of cobalt-60 will show two characteristic lines, the so-called gamma lines as shown in

**Figure 2** (A) Decay scheme of cobalt-60. The decay scheme shows the transition from a high to a lower energy state and the alteration of the composition of the atomic nucleus. The atomic number (number of protons in the atomic nucleus) for cobalt changes to the atomic number of nickel due to the emission of a negatively charged beta particle and neutron is transformed to a proton. (B) Gamma spectra of cobalt-60. The spectra show the characteristic gamma lines of cobalt-60 (1.17 and 1.33 MeV). The two spectra are produced by two different radiation detector types. Broad peaks (poor resolution) are due to a scintillation detector (sodium iodide) and narrow peaks (good resolution) are due to a semiconductor detector (germanium of high purity).

**Figure 2B.** Such a gamma spectrum is a clear evidence for the presence of cobalt-60. A quantitative determination is done by measuring the intensity of the gamma lines, the area under the peaks.

In a gamma spectrum some other lines can also be found that are not directly related to the decay process but are due to the interaction of gamma radiation with matter. This interaction is a rather complex process. Some knowledge of the interaction will help to understand the structure of a gamma spectrum.

## Interactions of Gamma-Rays with Matter

Gamma spectra are more complex than is expected just from the energies of a gamma transformation of a radionuclide. Therefore, the correct interpretation of the features of a gamma-ray spectrum as recorded with a gamma-ray spectrometer is an important skill. To understand this, some knowledge regarding the interactions of gamma-rays with matter is necessary. There are three major modes of interaction of gamma-rays with matter: photoelectric effect, Compton scattering, and pair production.

### Photoelectric Effect

In the photoelectric effect, the gamma-ray interacts with an electron of the inner shell of an atom of a radiation-absorbing material by transferring its energy totally to that electron. This results in the complete disappearance of the gamma photon and the ejection of an electron with energy equal to the energy of the initial gamma photon minus the binding energy of the electron. This binding energy is much smaller compared to the energy of the interacting gamma photon. The ejected electron can then induce events in a detector material. The electron gap in the inner shell is filled up by an electron of another shell and thus an X-ray photon is emitted.

The probability of the occurrence of photoelectric effect is related to the atomic number of the radiation-absorbing material and inversely related to the energy of the gamma-ray. Most frequently photoelectric absorption occurs with absorbing material of high atomic number and with low energies of the gamma-rays. The peak in the gamma-ray spectrum produced by detecting photoelectrons is called a full-energy peak because it provides immediate information about the energy of the gamma radiation (see Figure 3).

### Compton Scattering

A gamma photon may also interact with an electron of an atomic shell in such a way that it is scattered

**Figure 3** Schematic picture of a gamma spectrum of a radionuclide emitting gamma photons of a high single energy. The spectrum shows the photo-peak (or full-energy peak), corresponding to the energy of the characteristic gamma line of the radionuclide. By Compton scattering electrons with a wide energy distribution are produced (Compton continuum). By pair production and subsequent annihilation of the positron–electron pair a peak of 0.511 MeV (annihilation peak) is produced. If the gamma photons of 0.511 MeV escape from the detector without interaction a single and double escape peak appear in the spectrum.

and loses only part of its energy. The gamma-ray, now with less energy, is deflected from its initial path and the electron is ejected and may induce events in a detector material like a photoelectron, but these effects will be smaller compared with the total energy of the initial gamma-ray. If the scattered gamma-ray will produce a photoelectron within the detector material again a full-energy peak will be shown in the spectrum because the full energy of the gamma photon is dissipated in the detector material. But it is also possible that the scattered gamma-ray will escape from the detector without being detected. Then, only the dissipated energy of the scattered electron (Compton electron) contributes to the gamma spectrum. Because of the various scattering angles the Compton electrons show a distribution of energies over a wide range. This is called the Compton continuum. There is some gap between the full-energy peak and the Compton continuum (Compton edge or shoulder) corresponding to the minimum energy that is taken away by a back-scattered gamma photon (see Figure 3).

Compton scatter is most likely to occur in materials with high atomic number and for gamma-rays with energies from 0.6 to 4.0 MeV.

### Pair Production

Pair production occurs only for gamma-rays of high energy. By that effect the gamma-ray is transformed to matter in the form of a pair of negatively and

positively charged electrons (negatron and positron). Because an electron has a rest mass equivalent to 0.511 MeV of energy, a minimum gamma-energy of 1.02 MeV is required for this pair production. Any excess energy of the pair-producing gamma-ray is given to the electron–positron pair as kinetic energy. Most probably the positron will undergo annihilation by reaction with an electron in the detector material and by that two gamma photons of 0.511 MeV each will be created.

## Gamma Spectrum

Several additional peaks will appear in a gamma spectrum created by a high-energy gamma radiation. For a high-energy gamma-ray having produced an electron–positron pair, a full-energy peak will be displayed if all the energies of the electron–positron pair including the annihilation photons are dissipated in the detector material. But one of the annihilation photons or both of them may escape from the detector taking away 0.511 or 1.02 MeV of energy. As a consequence peaks related to lower energies than the full-energy peak will appear in the gamma spectrum: a single (or first) escape peak (full-energy peak minus 0.511 MeV) and a double (or second) escape peak (full-energy peak minus 1.02 MeV) are displayed in the spectrum.

Figure 3 is a schematic picture of a gamma spectrum related to a high-energy gamma radiation. Additional low-energy peaks caused by X-rays that are produced by fluorescence interactions with the shielding material of the detector may also appear. Lead X-rays occur in the regions from 74 to 88 keV.

It is possible that two gamma photons from the radioactive material are entering the detector simultaneously and are recorded as a gamma radiation with an energy equal to the sum of the two gamma energies. The resulting spectral feature would be a peak at energy equal to the sum of the individual incident gamma photons (sum peak). This phenomenon is observed at high radiation intensity and with small distances between radiation source and detector. A sum peak may be distinguished from a real full-energy peak by increasing the distance between source and detector. A sum peak will disappear but not a real full-energy peak.

## Detectors for Gamma Radiation

### Scintillation Detectors

Scintillation detectors emit photons of ultraviolet and visible light due to interaction of radiation emitted by radioactive materials.

Solid scintillation had been used earlier in nuclear science for the detection of radiation. The phenomenon of solid scintillation was discovered by Sir William Crookes in 1903. He exposed a layer of zinc sulfide to a sample emitting alpha particles and observed flashes of light. This effect later on was used for the assay of alpha radiation by visible counting of the light flashes. Many other scintillating crystalline substances useful for the detection of alpha particles, beta particles, gamma-rays, and even neutrons were discovered and applied. The application of solid scintillation for radiation detection and measurement can be found in most fields of nuclear science, and, of course, also in nuclear analytical techniques. For the measurement of gamma radiation, solid scintillation crystals of substances with high atomic number are used because of their so-called high stopping power. Among all the substances that are described in the literature, sodium iodide crystals are presently the most popular and most commonly used scintillation detector material for the measurement of gamma radiation. The sodium iodide crystal lattice contains a small amount of thallium that is introduced into the crystal lattice to serve as centers of activation to enhance luminescence.

The employment of solid scintillation detector materials like thallium-activated sodium iodide detectors for the measurement of gamma radiation requires the conversion of the visible photon emission of the scintillator to voltage pulses.

A photomultiplier tube with a photosensitive cathode and a series of dynodes is nowadays most frequently used for the detection and measurement of any photon-emitting process. Therefore, this type of equipment is also applied for counting the light flashes emitted by scintillation-detecting materials. The interaction of gamma radiation with the scintillator material produces light flashes and this visible light is converted to an electronic signal through a voltage pulse. The voltage pulses are processed further by electronic circuits to provide information about the spectral distribution of the energy of the gamma radiation.

### Semiconductor Detectors

The principle of operation of this type of detector can be explained by the band structure of the electrons in the semiconductor crystal. The band gap of some semiconductor materials is very small, for germanium  $\sim 0.66$  eV. A passage of radiation may inject sufficient energy into the structure to raise an electron from the valence band to the conduction band. By this an electron-hole pair is created. The expression 'hole' has to be understood as the absence

of an electron. This electron-hole pair can be compared with an ion pair in a gas ionization counting tube. Both the electron and the hole can migrate through the semiconductor crystal in response to an electric field and can produce an electrical signal that indicates the passage of radiation.

Lithium drifted germanium detectors were in use during the first years of semiconductor detectors' application for gamma-ray spectrometry. They showed good resolution and efficiency but had to be kept at the temperature of liquid nitrogen all the time.

Nowadays, it is possible to produce semiconductor detectors made of germanium crystal materials with very high purity. This type of detector is called a high-purity germanium (HPGe) or intrinsic germanium detector. Without being connected to voltage supply they can be stored at room temperature all the time. They still have to be cooled to liquid nitrogen temperature for operation. The detector crystal is enclosed in a Dewar vacuum housing and connected by a copper rod (cold finger) to a reservoir of liquid nitrogen. **Figure 4** shows a schematic diagram of a semiconductor detector system cooled with liquid nitrogen. Portable germanium detectors with a small cryostat are even used for field work. The HPGe detectors nowadays have largely replaced the lithium drifted germanium Ge(Li) detectors. The high price of semiconductor detector materials is considered as one of the main disadvantages.

Due to the development of solid-state semiconductor detectors great progress with regards to spectral resolution had been achieved in gamma-ray spectrometry. By the use of these detectors spectra with excellent resolution are obtained.

**Figure 4** Schematic cross-sectional view of a semiconductor detector for gamma-ray spectrometry with liquid nitrogen Dewar.

Semiconductor detectors are usually made of germanium for the measurement of high-energy gamma radiation or of silicon for low-energy gamma- and X-rays.

## **Electronic Circuits for Pulse Handling**

An electronic preamplifier circuit is coupled with a semiconductor detector or a photomultiplier of the scintillation detector as close as possible to minimize any pulse degradation due to cable capacitance. The preamplifier amplifies the electronic pulses by increasing the signal-to-noise ratios before the pulses enter a cable leading to an amplifier. In addition, the preamplifier output pulses may be linearly amplified and shaped by a pulse-shaping circuit. By this unit the tailing of the preamplifier output pulse is removed and uniformly shaped output pulses of different magnitudes are produced. The magnitude of a pulse depends on the number of photons of a light flash created within the scintillation detector or the number of electron-hole pairs created within the semiconductor detector. Both the number of photons and the number of electron-hole pairs depend on the energy dissipated within the detector by a gamma-ray. Therefore, the magnitude of a pulse is a function of the gamma-ray energy. The number of pulses per unit of time is a function of the number of gamma-rays emitted by the radiation source. The number of gamma-rays emitted per unit of time by a radiation source is related to its activity in becquerel. Thus, the output signals of the amplifier provide information about the activity of the radiation source and the energy of the emitted radiation.

## **Pulse Height Analyzer**

### **Single Channel Analyzer**

There is a linear correlation between the gamma-ray energy dissipated in the detector and the amplitude of the output pulse of the amplifier pulse. To make use of the available information a pulse discriminator is connected with the counting system. A pulse discriminator is an electronic gate that permits pulses of a certain magnitude to continue on in the circuit to be counted. To select pulses of a well-defined magnitude two discriminators are used: a lower level discriminator and an upper level discriminator. Only pulses can pass the system that are high enough to overcome the lower level discriminator but also low enough to pass the barrier set by the upper level discriminator. The heights of the lower and upper level discriminators are set in such a way that a so-called window or channel is created that can only be passed

by pulses of a selected pulse height interval. In this way, only pulses that are related to a selected radiation energy interval are registered and counted. This can be used to measure the intensity of a specific gamma-ray energy region emitted by a radioactive sample, but this method is too time-consuming for spectrometric investigations. It is also too complicated to apply many such windows simultaneously for a spectrometric measurement and therefore another approach is used for multichannel analysis.

### **Multichannel Analyzer**

To make efficient use of the high-energy resolution of modern semiconductor detector systems a large number of analyzer channels is necessary. This can be achieved by an analog-to-digital converter, e.g., by conversion of the pulse height into a pulse length. The pulse length can then be measured digitally by means of a frequency standard. The digital result is used for storage at a corresponding address register. Nowadays, multichannel analyzer systems with at least 4000 or 8000 addresses are state of the art. This type of gamma-ray spectrometry is used for qualitative and quantitative analysis of gamma-emitting radioactive materials.

Gamma-ray spectrometers are either constructed as stand alone or hardware gamma spectrometers, or are connected with a computer or even simple boards in a computer. Excellent computer software is available for data processing to perform qualitative and quantitative analysis of gamma-emitting radionuclides. An example for a multichannel analysis of an environmental sample is shown in **Figure 1**.

## **Comparison of Detector Properties**

Detectors for gamma-ray spectrometry are usually characterized by their resolution, efficiency, and peak-to-Compton ratios.

Resolution is the ability to distinguish between closely spaced peaks in a spectrum. The resolution is given as the value of the full width of a peak at half of its maximum height (FWHM). This value is given in keV for a selected full-energy peak, usually for the 1332 keV peak of cobalt-60. Sometimes resolution is defined as a percentage of the absolute peak position. The shape of a peak and also the resolution is influenced by the count rate.

The efficiency is the quotient of the number of events (counts) registered by the detector and the number of gamma photons of given energy emitted by the radiation source.

Sodium iodide detector crystals give good efficiency for gamma-ray detection due to the high atomic

number of iodine. This is because of a large fraction of interactions by photoelectric effect. Sodium iodide crystals are available in many configurations from small crystals up to large detectors coupled with multiple photomultiplier tubes. Well-type configurations permit good counting geometry for small samples.

Sodium iodide crystals show good efficiency but rather limited spectral resolution. The peaks of a gamma spectrum from a sodium iodide crystal are rather broad. Peaks generated from gamma-rays with energies close together cannot be separated. This is a big problem if radioactive materials with many different gamma-ray energies or mixtures of gamma-emitting nuclides have to be analyzed. It may also be difficult to distinguish small peaks from a Compton or background continuum that superimposes the weak peaks.

Bismuth germanate detectors have even better efficiency than sodium iodide detectors but their energy resolution is poor. Therefore, this type of detector material is used for special purposes but not for spectrometry.

For analytical purposes particularly in the analysis of complex gamma spectra having many closely spaced peaks semiconductor detectors are used. They have excellent resolution but lower efficiency because of their lower atomic number. In addition, the volume of available semiconductor detectors is usually much smaller compared to sodium iodide detectors. Both of these limits result in much lower detection efficiency.

The efficiency of a semiconductor detector is described as a relative efficiency compared with a standard detector, which is a NaI(Tl) crystal, with a diameter of 3 in. and a length of 3 in. being exposed to a point source of radioactive material at a distance of 25 cm.

The peak-to-Compton ratio refers to the ratio of the number of counts in the 1332 keV peak of cobalt-60 compared to the number of counts in the Compton region. Germanium detectors usually have a resolution better than 2 keV at Cobalt-60 1332 keV, relative efficiencies are mostly smaller but can be ~100% or better, and peak-to-Compton ratios show values up to 50.

## Calibration of Gamma-Ray Spectrometry Equipment

### Energy and Efficiency Calibration

In gamma-ray spectrometry the pulse height scale has to be calibrated in terms of absolute energy in keV to identify unknown gamma-ray emitters. For this purpose the channel position of the maximum of each

**Table 1** Gamma-ray sources used for calibration of gamma-ray spectrometer systems

<i>Radionuclide</i>	<i>Gamma energy (keV)</i>	<i>Gamma photons per decay</i>	<i>Half-life</i>
<sup>109</sup> Cd	88.0	0.05	453 days

<sup>60</sup> Co	1173.2	1.00	5272 years
<sup>22</sup> Na	1274.6	1.00	2602 years
<sup>60</sup> Co	1332.5	1.00	5272 years

photo peak must be plotted versus the gamma-ray energy. A best fit through these data gives the energy corresponding to each channel in the multichannel analyzer. With good detectors a straight line is obtained; However, due to inherent nonlinearities in the detector or recording system this calibration may not be perfectly linear or pass exactly through the origin of the diagram.

For calibration of a gamma-ray spectrometry equipment a set of calibrated gamma-ray sources is necessary to determine various parameters like energy scale, efficiency, resolution, geometric effects, etc. Usually the activity of a calibrated source is given by the number of disintegrations per second (becquerel) or curie ( $1 \text{ Ci} = 3.7 \times 10^{10}$  disintegrations per second). The number of emitted gamma-rays per second is frequently less than the number of disintegrations depending on the branching ratio of the decay.

In Table 1, a list of radionuclides, their gamma-ray energies, and the fraction of gamma-rays per decay is listed. Such sets of gamma calibration sources are commercially available. The radionuclides are available either as point sources or as solutions. With point sources, the sample geometry cannot be changed whereas solutions of radionuclides can be filled in various containers like those that are used for the measurement of, e.g., environmental samples.

Catalogs of experimental measured gamma-ray spectra with both types of detectors, sodium iodide and semiconductor, have been published in the literature. This type of compilation is very useful for the prediction of the suitability of the detector types for a special application.

## Gamma-Ray Spectrometry in Quantitative Radionuclide Analysis

Gamma spectra are of great help for qualitative and quantitative analysis of radioactive samples of unknown composition.

The following method gives a simple example of how to perform a quantitative spectrum analysis. In any method, the number of integral (summation) counts of a photo-peak is proportional to the gamma-rays incident upon the detector. The total number of counts is displayed by the area of a photo-peak and this area has to be calculated. Nonoverlapping single peaks show a clear Gaussian shape. But the total area of a peak depends on the contributions of both the gamma photons from the sample and the gamma photons due to the background radiation and the Compton continuum of higher energetic peaks. Therefore, to obtain the contribution of the gamma-rays of the sample the contribution of the background radiation has to be subtracted. This background contribution to the peak area has the shape of a trapezoid. This trapezoid area can be easily calculated using the address (channel) numbers of the lower ( $L$ ) and higher ( $H$ ) end of the peak and the amount of counts being registered in the lower ( $n_L$ ) and in the higher ( $n_H$ ) address positions (channels). This is demonstrated by **Figure 5**

$$B = (H - L + 1) \cdot \frac{(n_L + n_H)}{2}$$

The area corresponding to the background contribution is subtracted from the total area, represented by the total number of counts being stored in all the channels from  $n_L$  to  $n_H$ . Very frequently this

**Figure 5** Determination of the net area of a peak in a gamma spectrum.  $T$  is the total peak area,  $L$  the lower end of the peak,  $H$  the higher end of the peak,  $B$  the contribution of the background to the total peak area,  $N$  the net peak area due to sample activity,  $n_L$  the counts being registered in the channel of the low end of the peak, and  $n_H$  the counts being registered in the channel of the high end of the peak:  $B = (H - L + 1) \cdot (n_L + n_H)/2$  and  $N = T - B$ .

calculation is much more complicated if there are fluctuations of channel contents in the neighborhood of channel  $n_L$  and  $n_H$ . In this case average values considering the relevant channel regions have to be calculated. To resolve overlapping peaks and construct their individual Gaussian shapes sophisticated and powerful computer programs have been developed. The interpretation of gamma spectra for quantitative analysis using computer programs nowadays has reached a very high standard of reliability and precision.

Finally, the radioactivity of a sample has to be calculated considering the counting efficiency of the detector for the gamma energy in question.

The simplest and most reliable method to determine the radioactivity will be the relative method in which the peak counting rate of a sample is compared quantitatively with that of the radioactive standard consisting of the same nuclide and geometry. Usually, the peak efficiency for each detector is prepared by means of experimental procedures using various kinds of radioactive standards. But theoretical methods based on Monte Carlo theory have also been designed.

## Special Types of Gamma-Ray Spectrometric Equipment

### Anti-Compton Spectrometers

One of the main problems in the interpretation of gamma spectra is the correct detection of low-level radioactivity in the presence of a high background. Such a high background can be due to a Compton continuum that is associated with an intense high-energy gamma peak. The detection of a small peak that may be situated in the region of such a Compton continuum is difficult. Such a problem can be avoided by the application of Compton suppression techniques. The best Compton suppression can be achieved by surrounding the detector for sample measurement by a so-called guard detector system. Most frequently sodium iodide or other scintillation detectors are used as guard detectors. Compton electrons are registered simultaneously by the guard system and by the detector facing the radioactive sample. This coincident information is subtracted from the information obtained by the detector for sample measurement. Thus, the background in the Compton region is reduced. By this method the Compton effect contribution is minimized and a peak-to-Compton ratio of 450:1 can be obtained.

Such a system is very helpful for environmental radioassay related to radionuclides with very low concentration in nature.

### Coincidence Spectrometers

Coincidence spectrometers are used for selectively measuring nuclear processes that occur with practically simultaneously emitting two gamma-rays of different energy or beta and gamma radiation within a very short time interval. By this selective measurements technique a radiation of low intensity in presence of an accompanying high-intensity radiation can be detected with reasonable sensitivity.

### Applications of Gamma-Ray Spectrometry

Nowadays gamma-ray spectrometry is the most important tool for radio assay. Quality control in radionuclide production, control of reactor operation, surveillance of the environment, and radio activation analysis are only a few examples for the application of gamma-ray spectrometry.

It has to be mentioned that the international control of nonproliferation of fissile materials and the

verification of the nuclear test ban treaty are mainly based on the application of gamma-ray spectrometric methods.

### Introduction

Radiochemical analysis is based on two outstanding features of radioactivity:

1. the high sensitivity and ease of measurement of radioactive radiation; and
2. the possibility of labeling chemical compounds with radioactive tracers.

Radionuclide techniques often have higher sensitivity than other analytical methods. The amounts of nuclides, correlated to an activity of 1000 Bq (see Table 1), can be derived from the law of radioactive decay. The amounts vary considerably, corresponding to the wide range of half-lives. For 90% of the commonly used nuclides, half-lives range from several minutes to several years, so the corresponding masses are extremely low.

Radionuclides are often diluted with inactive isotopes, but specific activities (i.e., activity per total mass of element) are still very high. Since the

background in nuclear spectrometry is very low, and sensitivity is high, activities as low as 0.2 Bq can be readily detected ( $^3\text{H}$ ,  $^{125}\text{I}$ ,  $^{132}\text{I}$ ), and even 0.01 Bq (several  $\gamma$ -emitters, e.g.,  $^{24}\text{Na}$ ,  $^{38}\text{Cl}$ ,  $^{42}\text{K}$ ,  $^{46}\text{Sc}$ ,  $^{59}\text{Fe}$ ,  $^{60}\text{Co}$ ,  $^{65}\text{Zn}$ ,  $^{110\text{m}}\text{Ag}$ ,  $^{182}\text{Ta}$ ,  $^{187}\text{W}$ ,  $^{198}\text{Au}$ ). Total activities  $\sim 0.1$ – $20$  kBq are often sufficient in

### Introduction

Radiochemical analysis is based on two outstanding features of radioactivity:

1. the high sensitivity and ease of measurement of radioactive radiation; and
2. the possibility of labeling chemical compounds with radioactive tracers.

Radionuclide techniques often have higher sensitivity than other analytical methods. The amounts of nuclides, correlated to an activity of 1000 Bq (see Table 1), can be derived from the law of radioactive decay. The amounts vary considerably, corresponding to the wide range of half-lives. For 90% of the commonly used nuclides, half-lives range from several minutes to several years, so the corresponding masses are extremely low.

Radionuclides are often diluted with inactive isotopes, but specific activities (i.e., activity per total mass of element) are still very high. Since the

background in nuclear spectrometry is very low, and sensitivity is high, activities as low as 0.2 Bq can be readily detected ( $^3\text{H}$ ,  $^{125}\text{I}$ ,  $^{132}\text{I}$ ), and even 0.01 Bq (several  $\gamma$ -emitters, e.g.,  $^{24}\text{Na}$ ,  $^{38}\text{Cl}$ ,  $^{42}\text{K}$ ,  $^{46}\text{Sc}$ ,  $^{59}\text{Fe}$ ,  $^{60}\text{Co}$ ,  $^{65}\text{Zn}$ ,  $^{110\text{m}}\text{Ag}$ ,  $^{182}\text{Ta}$ ,  $^{187}\text{W}$ ,  $^{198}\text{Au}$ ). Total activities  $\sim 0.1\text{--}20\text{ kBq}$  are often sufficient in

**Table 1** Mass corresponding to 1 kBq for carrier-free radionuclides

Nuclide	Mass <sup>a</sup> (ng)	Half-life <sup>b</sup>
$^{36}\text{Cl}$	820	$3 \times 10^5\text{ a}$
$^{14}\text{C}$	6.1	$5.8 \times 10^3\text{ a}$
$^{63}\text{Ni}$	0.57	120 a
$^{85}\text{Kr}$	$6.8 \times 10^{-2}$	10.6 a
$^{125}\text{I}$	$1.6 \times 10^{-3}$	60 d
$^3\text{H}$	$2.8 \times 10^{-3}$	12.4 a
$^{131}\text{I}$	$2.2 \times 10^{-4}$	8.04 d
$^{35}\text{S}$	$6.3 \times 10^{-5}$	87.2 d
$^{32}\text{P}$	$9.5 \times 10^{-5}$	14.3 d
$^{99\text{m}}\text{Te}$	$5.1 \times 10^{-6}$	6.02 h
$^{18}\text{F}$	$2.8 \times 10^{-7}$	1.83 h

<sup>a</sup>Commercially available with maximum specific activity of  $2 \times 10^4\text{ Bq g}^{-1}$ .

<sup>b</sup>a = year (annum).

analytical applications. The precision of the final result can be better than 2%, if the counting error is kept below 1.5%. This can be obtained from counting times between 100 s and 5 h.

Radiochemical analysis relies on the assumption that different isotopes of the same element exhibit the same properties in any macroscopic physical or chemical process, and that radioactive labeling does not influence the other properties of a chemical species. This is generally the case, with deviations below 1% (with exception of hydrogen isotopes) owing to isotopic fractionation or radiation effects. For analytical purposes, the radiotracer and the analyte must be present in the same chemical form. This is usually easy to achieve, but specialized preparative techniques may be necessary for radioactive labeling of more complex organic compounds.

Measurements of ionizing radiation and radionuclides in foods and environmental samples are required for the assessment of exposure to both natural and artificial radiation sources, determination of compliance with government regulations, and studies of the movement and retention of artificial radionuclides in food and environmental media and of the composition of the natural radiation environment.

A wide assortment of equipment and methods are available with which to:

1. monitor the presence and ecological behavior of radionuclides that are present in food and environmental samples;
2. identify the pathways by which human exposure results; and
3. estimate the dose to humans.

The selection of foodstuffs depends on the behavior of analytes in the food chain and the eating habits of local populations. Materials frequently analyzed for radioactive contamination include food crops (fruits and vegetables), milk (cow and goat), domestic animals (deer, rabbits, and squirrels), and game birds (pheasant).

Laboratory measuring equipment used in radiochemical analytical procedures should show a high radiation sensitivity, high detection efficiency, low background, and high stability.

Counting rates measured with Geiger-Müller, scintillation, or semiconductor detectors are usually compared with suitable standards to obtain quantitative data. Pulse analyzers (either single or multichannel), when coupled to a suitable radiation detector, can yield qualitative as well as quantitative data about individual components of the sample.

## Preparation of Labeled Compounds

Aspects of the labeled substance involve the following requirements:

1. Radionuclide and radiochemical purity are essential. The labeled substance must react identically to the analyte.
2. Complete homogenization and isotope exchange must be achieved, requiring successive transformation of the active traces as well as of the inactive analyte to all chemical species that are considered to occur in the complete system.
3. Isotope effects must be negligible.
4. For most elements, suitable radionuclides for analytical use are commercially available. There are only seven elements of interest (B, He, Li, N, Ne, O, Mg), for which this is not the case.
5. The preparation of a specific isotope, of an isotopically modified (i.e., mixture of labeled and unlabeled), isotopically substituted, or even site-specifically labeled compound is often mandatory in analytical applications.
6. Synthesis (including biosynthesis) of these labeled compounds often requires much more effort than the actual radioanalytical experiment. A variety of labeled compounds and pharmaceuticals are available commercially from stock, and a further range of compounds will be prepared on request by a number of suppliers.
7. Cost of radionuclides for analytical applications are typically in the range US\$150–400 per 40 MBq, and higher where preparation is difficult or time consuming.

Synthesis of labeled compounds involve all of the classical biochemical and synthetic chemical reactions used in the preparation of nonradioactive chemicals.

Synthetic chemical methods for the preparation of carbon-14-labeled chemicals utilize a number of basic building components that are prepared from barium carbonate ( $^{14}\text{C}$ ). These are  $^{14}\text{C}$  versions of carbon dioxide, acetylene, benzene, sodium acetate (1- and 2- $^{14}\text{C}$ ), methyl iodide, methanol, sodium cyanide, and urea. Many complicated labeled compounds may be synthesized from these materials.

Isotope exchange can be used when the substance to be labeled is readily obtainable in the inactive form and conditions favorable for the exchange, e.g., temperature and exchange rate, can be found. This is so, for example, for Bengal rose and thyroxine, both of which may be labeled by exchange with  $^{131}\text{I}_2$ . The starting material must be free from iodinated or already iodinated compounds whose exchange rates are roughly equal to or greater than the rate of the

desired reaction. For preparative purposes, the isotope exchange method is largely confined to the elements bromine and iodine.

Biosynthetic methods are ideally suited for the synthesis of many radiolabeled compounds. Plants (e.g., potato and tobacco), when grown in the atmosphere of radioactive carbon dioxide utilize the  $^{14}\text{CO}_2$  as their sole source of carbon. After a suitable period of growth, almost every carbon atom in the plant is radioactive. In this way plants can serve as a source of labeled carbohydrates. Algae grown under similar conditions provide labeled amino acids, lipids, nucleotides, etc. Vitamin  $\text{B}_{12}$  is obtained from the metabolic products of microorganisms whose culture media contain cobalt-57 or cobalt-58.

Labeling with tritium ( $^3\text{H}$ ) is most commonly achieved by reductive methods, including catalytic reduction of olefin by deuterium gas ( $^3\text{H}_2$ ), catalytic reductive replacement of halogen by  $^3\text{H}_2$ , and metal hydride ( $^3\text{H}$ ) reduction of carbonyl compounds to tritium-labeled alcohols.

## Nonchromatographic Methods of Analysis

In general, there can be considered to be three working stages in radiochemical analysis:

1. sample preparation,
2. chemical separation, and
3. radioactivity measurement.

Following sample preparation, the element whose radioisotope (or labeled compounds) is to be determined is separated from the sample. The final measurement of the activity of the element (or labeled compounds) is made on the isolate.

One of the main differences between radiochemical analytical procedures and classical analytical methods is that the element (and particularly its radioisotope) to be determined is present in the sample in minor to trace amounts. Separation of radionuclides is performed with the aid of a suitable carrier. Generally, the carrier is a stable isotope (or a suitable compound) that is added to the radioactive compound in a small but detectable amount and has identical chemical properties. An isotopic carrier, i.e., a stable isotope of the element in question, is most frequently used. Both the radioactive isotope and the carrier must be in the same chemical form. The isotopic carrier is irreversibly mixed with the radioactive compound and cannot be separated from it again by chemical means. Such a carrier can therefore be used only when a lower specific activity is sufficient for the subsequent operations. For example, barium or lead can serve as carriers when

separating radium; iron or yttrium may be applied in separations of rare-earth elements, etc. In certain cases, when no stable isotope is available, e.g., as in plutonium separation, a separation of carrier-free radionuclide is also possible.

Essentially all the separation methods known from classical analytical chemistry can be applied to chemical separations of radionuclides and labeled compounds from samples to be analyzed: precipitation, electrolytic deposition, extraction, ion exchange, distillation, chromatography, etc.

As only small absolute amounts of radionuclides are to be determined, and thus only small amounts of elements are to be separated, separation cannot usually be properly performed by methods whose success depends on the amount of the component to be isolated (e.g., as in precipitation). Therefore, methods that are independent of amount (such as liquid-liquid extraction and ion-exchange methods) are more advantageous. Extraction procedures very often take advantage of additions of chelating components. For separating volatile radionuclides (such as iodine or ruthenium) from the sample matrix, distillation methods can be used advantageously. Electrolytic deposition has been shown to be applicable in the separation of polonium.

In contrast with precipitation procedures, these specific methods are time saving and allow the separation of carrier-free radionuclides. Radiochemical methods of determining radionuclides show the highest sensitivity. Radiochemical methods for determining fission products were originally devised for treating high-activity solutions; however, they are not always convenient for the determination of very small concentrations in biological materials. Radiochemical analytical procedures have been developed for those cases where the radionuclides should be separated from large amounts of stable salts after ashing the sample. Among fission products, strontium-90 is of vital importance; the determination of the other products is of minor significance.

The methods used for the detection and quantification of radionuclides and labeled compounds are determined by the type of emission ( $\beta$  or  $\gamma$ ), the energy of the radiation, and the efficiency of the system by which it is measured. Commercially available instrumentation is generally used, with exception of some research work and highly specialized routine analytical application. Detection of radioactivity can be achieved in all cases with the Geiger-Müller counter. However, for the weaker-emitting radionuclides, i.e.,  $^3\text{H}$ ,  $^{14}\text{C}$ , and  $^{35}\text{S}$ , large amounts of radionuclides are required for detection of a signal. In most cases this is both undesirable and impractical.

Liquid scintillation counting is by far the most common method of detecting and quantifying low-energy  $\beta$ -radiation. A less common technique is planchette counting. A film of the sample on a planchette, which is a flat metal pan, is brought within a fixed distance of a Geiger–Müller counter.

The detection and quantification of  $\gamma$ -radiation is accomplished by well counting in a scintillator, the sample being contained in a well or drilled hole.  $\gamma$ -Radiation is often measured by  $\gamma$ -ray scintillation or semiconductor spectrometry. Gas flow counting is a method for detecting and quantifying radionuclides on paper chromatographic strips and thin-layer plates.

The detection limit (DL) of the concentration of the analyte is given by

$$DL = \frac{f}{s} \sqrt{B}$$

Here  $f=3$  is appropriate for detection at the 99.9% confidence level,  $B$  is the blank level, including analytical blank and spectral background of the detection device, and  $s$  is the analytical calibration function, i.e., under idealized conditions:

$$s = \varepsilon \eta t a m_{\text{sample}}$$

where  $\varepsilon$  is the detection efficiency,  $\eta$  is the emission probability,  $t$  is the counting time,  $a$  is the specific activity of the analyte, and  $m_{\text{sample}}$  is the mass.

Specimen preparation for radioactivity measurements aims, in general, to obtain the analyte:

1. As completely as possible and with the highest possible degree of purity from extraneous radioactivity and from excess matrix matter.
2. Concentrated on the smallest area or volume of a solid, liquid, or gaseous (for H, C, S, Ar, Kr, Xe, Rn) target.
3. On a specimen support that is compatible with the chemical nature of the species analyzed, with the specific radiation to be measured, and with the detector system, e.g., liquid scintillation cocktails for weak  $\beta$ -emitters.

These preparation requirements are compatible with the more general rules for specimen preparation in trace and ultratrace analysis by any technique.

## Chromatographic Methods

Chromatographic methods are frequently used to separate radioactive nuclides and labeled compounds and can be used to analyze complex systems by using radioactive indicators. The principle of separation is the same as in standard chromatographic methods

but radiometric detection is used. It is possible to separate and detect radioactive compounds, compounds converted to radioactive derivatives, or compounds labeled with radioactive nuclides.

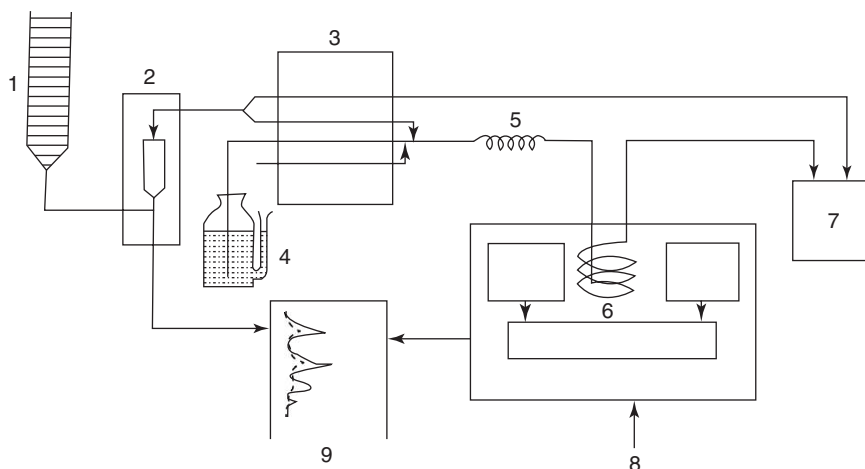

The detection of radioactivity is very sensitive, but there may be problems in manipulating the radioactive compounds because of contamination of various parts of the chromatographic system. Complete decontamination of those parts that have been in contact with radioactive compounds must be ensured. It is sometimes better to exchange inexpensive parts for new ones. Even small amounts of radioactive impurities can seriously interfere because of the high sensitivity of detection. The possibility of forming radioactive reaction products, such as tritiated water in reactions with compounds labeled with  $^3\text{H}$ , or  $^{14}\text{CO}_2$  in reactions with compounds labeled with  $^{14}\text{C}$ , must also be considered.

Considerable losses of samples with low concentrations of radioactive nuclides may occur because of adsorption on various parts of the chromatographic system. These difficulties can be overcome by the addition of a suitable carrier.

All chromatographic methods (liquid, liquid–liquid, liquid–solid, gas, gas–liquid, and gas–solid chromatography) are used in radiochemical analysis of food and environmental samples. Equipment for the evaluation of paper and thin-layer radiochromatograms is commercially available. The radiation detectors used vary according to the type and energy of the radiation emitted by the measured radionuclides. Use is made of ionization chambers, proportional counters, and Geiger–Müller, scintillation, and semiconductor detectors.

The measurement of radioactivity in chromatographic methods can be either discontinuous or continuous. Discontinuous analysis is a very simple method that depends upon measuring the radioactivity of the individual fractions of components that were separated in the column, chromatographic paper, adsorbent, etc. This method is used whenever the specific activities are very low and there is no time limit for the analysis. In this technique, however, results are obtained only after sometime and consequently parts of the fractions may be lost. In column chromatography fraction collectors are exchanged at regular time intervals or as soon as a detector (e.g., a standard ultraviolet (UV) absorbance detector) detects the passage of an analyte. The fraction is detected as soon as it leaves the column. A Geiger–Müller or a well-scintillator detector can be used for  $\beta$ -emitters (e.g.,  $^{32}\text{P}$ ) or  $\gamma$ -emitters. Semiconductor detectors can also be used to detect  $\beta$ -radiation. Cherenkov-type detectors are sometimes used for radiation of higher energy.

**Figure 1** Homogeneous measuring system (1 – column, 2 – UV detector, 3 – pump, 4 – scintillator, 5 – mixing chamber, 6 – flow cell, 7 – fraction collector, 8 – scintillation detector, 9 – recording device).

**Figure 2** Heterogeneous measuring system (1 – column, 2 – UV detector, 3 – flow cell, 4 – pump, 5 – fraction detector, 6 – scintillation detector, 7 – recording device).

In continuous analysis, radioactivity detectors are coupled serially with standard chromatographic detectors. The eluate passes through a suitable flow cell and the radioactivity is measured continuously. There are two types of measurements: heterogeneous and homogeneous. These two types of measuring systems for liquid chromatography are shown in **Figures 1** and **2**. In the heterogeneous mode, the measuring cell can be made of a scintillating material. Frequently used configurations are U-shaped cells packed with anthracene, scintillating lithium glass activated with cerium oxide, or other scintillators. For homogeneous measurements, the eluate is mixed with a liquid scintillator before entering the detector. The cell for homogeneous measurements is usually a spiral. It is placed between two photomultiplier tubes that are connected in a coincidence circuit.

Classical liquid radiochromatography has been used mainly for preparative work, and analytical applications have been rare. The method has been important in the separation and isolation of new radioactive elements and labeled compounds. Technical progress has made this method applicable to the direct analytical determination of biochemically important compounds, labeled preparations, components of food and environmental samples.

### Illustrative Examples from Environmental Science

Radioactive contamination can result from either expected or accidental release of radioactive materials during the treatment of uranium and thorium ores, the operation of nuclear reactors, or the

application of radionuclides and labeled compounds in medicine, research, industry, and agriculture, as well as from radioactive fallout from the atmosphere.

Man obtains food from three regions of the biosphere: seawater, the sweet water hydrosphere, and soil. Thus, radioactive contamination of these three regions represents the chief field of interest for radiochemical analysis.

Tritium in water samples is determined with a liquid scintillation spectrometer because of its low maximum  $\beta$ -particle energy (18 keV). Water samples are distilled to remove nonvolatile components whose presence could lead to extinction during the scintillation detection and could also be radioactive. The sample is distilled to dryness in order that the tritium present can be transferred quantitatively into the distillate. A portion of the distillate is mixed with the liquid scintillator, and the radioactivity is measured by a liquid scintillation spectrometer. A standard tritium sample and a sample for measuring the background are prepared in a similar way.

The radionuclide zirconium-95 ( $^{95}\text{Zr}$ ) can be found among direct products of nuclear fission. Its radioactive decay leads to the daughter niobium-95 ( $^{95}\text{Nb}$ ). In the determination of  $^{95}\text{Zr}$  and  $^{95}\text{Nb}$  in samples of seawater and sea plants, the samples are mixed with oxalic acid in order that zirconium and niobium complexes can be formed in the presence of nitric acid. The oxalic acid is destroyed with potassium chlorate, and zirconium and niobium are precipitated as zirconium phosphate and niobic acid, respectively. Activities of rare-earth elements are removed, and zirconium is separated as barium hexafluorozirconate and ashed to zirconium pentoxide. The niobium fraction is ashed to niobium pentoxide. Both radionuclides are finally determined by  $\gamma$ -ray spectrometry.

Radioruthenium enters plants because of direct contamination; however, it is usually concentrated in certain water plants, so that its determination is significant, particularly in regions where radioactive waste materials are stored in the sea. Ruthenium determination can be carried out by a simple and direct  $\gamma$ -ray spectrometric method. When it satisfies the other conditions, this procedure is rapid and economical. It is difficult to distinguish  $^{103}\text{Ru}$  and  $^{106}\text{Ru}$  because of their closely spaced  $\gamma$ -lines.

In many environmental samples, particularly those that are not contaminated with fission products, the radioiodine content can be determined by a direct  $\gamma$ -ray spectrometric method. The 364 keV  $\gamma$ -line is the most suitable for the spectrometric determination of radioiodine,  $^{131}\text{I}$ . Certain difficulties can be encountered when the radionuclides barium-140 and lanthanum-140 are present in the sample.

$\gamma$ -Ray spectrometry can also be employed for radium determination in seawater in combination with the separation with ammonium molybdophosphate.

A majority of the radiochemical methods for radium determination in environmental samples takes advantage of its isomorphous co-precipitation with barium as its sulfate. Very small amounts of the barium carrier are typically used to minimize the self-absorption of  $\alpha$ -particles from the radium.

Neptunium can easily be separated quantitatively from plutonium with the aid of anion exchangers. If both ions are in a concentrated hydrochloric acid solution, iodide ions are added to reduce plutonium to Pu(III) and neptunium to Np(IV). The solution then passes through a column filled with Dowex-1 anion exchanger. Plutonium is thus quantitatively eluted with concentrated hydrochloric acid, and neptunium can be desorbed with  $0.5 \text{ mol l}^{-1} \text{ HCl}$ .

## Illustrative Examples from Food Science

It was originally believed that radionuclides were introduced into the human organism by inhalation and/or through drinking water. Later it was shown that many radionuclides (e.g.,  $^{90}\text{Sr}$  and  $^{137}\text{Cs}$ ) came into the human organism only through food. Thus, attention should be paid not only to a study of the occurrence of radionuclides in air and water, but also to their determination in food and even in forage.

A study of milk contamination is of particular interest, since strontium, cesium, and iodine enter into the human organism only from milk.

Contamination of cheese usually has its origin in the presence of  $^{89}\text{Sr}$  and/or  $^{90}\text{Sr}$  in milk. Contamination of meat can mostly be attributed to  $^{137}\text{Cs}$ . Contents of either  $^{131}\text{I}$  in the thyroid gland of animals or  $^{89}\text{Sr}$  and  $^{90}\text{Sr}$  in their bones may serve as indicators of the degree of environmental contamination.

Labeled compounds offer many advantages for food science. The extreme sensitivity of radioactivity measurement enables one to determine and characterize biologically important trace elements and compounds (e.g., pesticides and pesticide residues) in food samples.

Many analytical methods have been developed for simultaneous radiochemical determination of several radionuclides, including  $^{89}\text{Sr}$ ,  $^{90}\text{Sr}$ ,  $^{140}\text{Ba}$ ,  $^{137}\text{Cs}$ ,  $^{131}\text{I}$ , and  $^{239}\text{Pu}$ , in a great variety of food samples, such as milk, corn, vegetables, fruits, fats, eggs, meat, etc.

Strontium-90 is commonly determined by measuring its daughter yttrium-90 ( $^{90}\text{Y}$ ) at the state of the radioactive equilibrium after the chemical separation. As radionuclides  $^{89}\text{Sr}$  and  $^{90}\text{Sr}$  emit no

$\gamma$ -radiation, they have to be separated from  $^{90}\text{Y}$  prior to their determination.

Strontium radioisotopes in milk can be determined by making use of an ion exchange procedure. The milk sample is allowed to stand for 2 weeks to achieve a sufficient  $^{90}\text{Y}$  accumulation. Citrate and both yttrium and strontium carriers are added. The solution is applied onto a column of cation then anion exchangers. Strontium and yttrium are retained on the cation and anion exchangers, respectively. Yttrium is washed out from the anion exchanger with hydrochloric acid and precipitated as yttrium oxalate. After weighing the precipitate and determining the chemical yield the  $\beta$  activity of the  $^{90}\text{Y}$  is measured. In the presence of  $^{140}\text{La}$  the yttrium oxalate is dissolved in concentrated nitric acid, and yttrium is extracted with tributyl phosphate. Lanthanum-140 remains in the aqueous phase. Yttrium is back-washed with nitric acid and precipitated as its oxalate. In an unfavorable case, i.e., when the amount of  $^{140}\text{Ba}$  exceeds by several orders that of  $^{90}\text{Sr}$ , the above separation procedure has to be repeated.

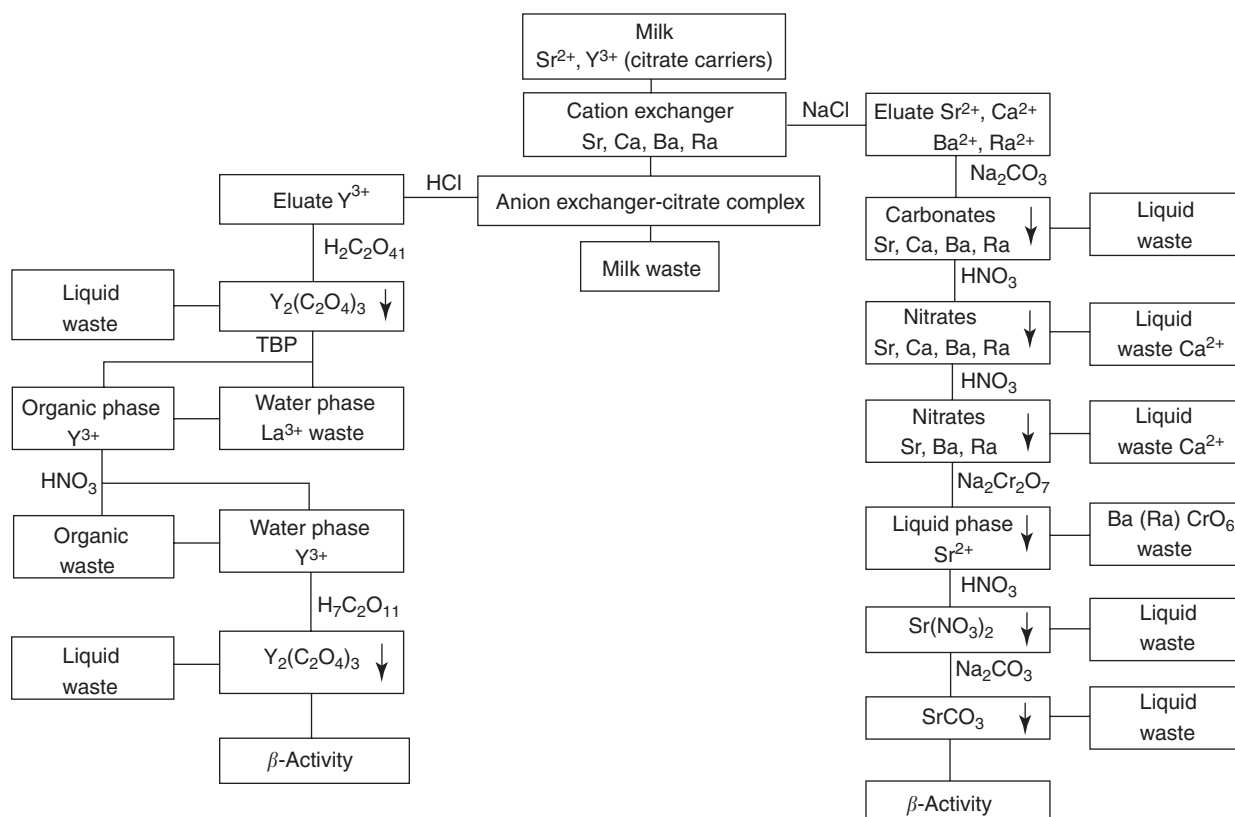

Strontium is washed out from the cation exchanger with a sodium chloride solution, concentrated in the eluate by precipitation as its carbonate, and purified through nitrate precipitation. Barium-140 and

radium are removed by chromate precipitation. When the strontium is precipitated as its carbonate, its chemical yield is determined, and the activity of all the radiostrontium is measured. The procedure for separating  $^{90}\text{Sr}$  and  $^{90}\text{Sr}$  from  $^{90}\text{Y}$  by ion exchange is shown in Figure 3.

The radioiodine ( $^{131}\text{I}$ ) content of milk can be determined on the basis of iodine extraction from milk with tetrachloromethane (carbon tetrachloride). In this way, only inorganic iodine in milk is determined, and organically bound iodine is obtained after alkali metal fusion and extraction. The activity is measured after the precipitation of silver iodide.

The  $^{137}\text{Cs}$  concentration in foods, plants, corn samples, etc., can be determined by direct measurement of radioactivity with a  $\gamma$ -ray spectrometer. This method requires a higher  $^{137}\text{Cs}$  concentration than in the radiochemical procedure, and radioactive impurities whose  $\gamma$ -rays have energies similar to that of cesium  $\gamma$ -rays (such as  $^{95}\text{Zr}$ ) can be present only in negligible amounts. The spectrometric method can be used either directly on the original sample or after concentrating  $^{137}\text{Cs}$ , depending on the detection efficiency and on the  $^{137}\text{Cs}$  concentration in the sample.

In the determination of uranium the food sample is decomposed with concentrated nitric acid, and

**Figure 3** Separation scheme for determining radiostrontium in milk by using ion exchange.

uranium is extracted with tributyl phosphate in paraffin. The solution of ammonium nitrate and iron(III) nitrate is employed as a salting-out agent. The organic phase is washed with nitric acid, and uranium is back-extracted into water, concentrated by evaporation, and its  $\alpha$ -activity is measured.

In aqueous food samples, plutonium can be separated by precipitation of bismuth phosphate and extraction of the cupferronate complex in chloroform. Finally, plutonium is precipitated by using an iron(III) carrier and measured by means of an  $\alpha$ -ray spectrometer.

Paper radiochromatography has been employed to determine vitamin B<sub>12</sub> labeled with cobalt-60 in foods, to follow its metabolism, and for various other studies. Thin-layer chromatography has been used for the determination of lipids labeled with <sup>3</sup>H, <sup>14</sup>C, or <sup>131</sup>I in foods.

Gas chromatography has been applied successfully to the separation and analysis of labeled compounds (chiefly those labeled with <sup>3</sup>H and <sup>14</sup>C) in food samples. Studies have been made of the biosynthesis of unsaturated fatty acids, the effect of insulin on the biosynthesis of individual fatty acids, the biosynthesis of cholesterol, etc. Numerous studies deal with the incorporation of labeled compounds through foods into living organisms.

### Introduction

Radioactive compounds can be used in medicine for the diagnosis or treatment of disease. A radiopharmaceutical is an unsealed source of radioactivity in liquid, gaseous, or particulate form, which has to be removed from its container before administration. This article will discuss the analytical methods used for quality control of radiopharmaceuticals.

Most, but not all, radioisotopes require a carrier molecule (ligand) to be transported around the body and localize into the tissue or organ of interest. The applicability of a particular radiopharmaceutical depends on both the radioisotope and the ligand. There

should be selective concentration in the target organ with fast clearance from surrounding tissues (e.g., blood) giving a high target-to-background ratio. **Table 1** shows some of the many radiopharmaceuticals currently in clinical use.

The ideal isotope for use in diagnostic imaging is a gamma or positron emitter. These emissions are penetrating and can be detected outside of the body by the imaging equipment. The isotope should have a short half-life to minimize the radiation dose to the patient. Other requirements are that it should be nontoxic, readily available, inexpensive to produce, and chemically reactive. Technetium (<sup>99</sup>Tc<sup>m</sup>) fulfills all of these requirements having a gamma energy emission of 140 keV, 6 h half-life, and ready availability via a generator system. Technetium (<sup>99</sup>Tc<sup>m</sup>) labeled products are usually produced in the radiopharmacy from cold kits (from a licensed manufacturer) to which the isotope is added after elution

from a generator. Following an incubation stage the product is ready to use without further purification. The kit is usually a lyophilized preparation containing ligand, reductant, and buffer. More recently, positron emitters such as fluorine ( $^{18}\text{F}$ ) have been introduced for use in positron emission tomography (PET). Radiopharmaceuticals for use in PET are

**Table 1** Examples of radiopharmaceuticals used in clinical practice

<i>Radiopharmaceutical</i>	<i>Example of clinical use</i>
Methionine ( $^{11}\text{C}$ ) injection	Imaging primary tumors and metastases in the brain
Fludeoxyglucose ( $^{18}\text{F}$ ) injection (FDG)	Imaging primary tumors and metastases
Chromium ( $^{51}\text{Cr}$ ) edetate injection	Determination of glomerular filtration rate
Yttrium ( $^{90}\text{Y}$ ) silicate injection	Radiation synovectomy agent
Technetium ( $^{99}\text{Tc}^{\text{m}}$ ) medronate injection	Bone imaging agent
Technetium ( $^{99}\text{Tc}^{\text{m}}$ ) mertiatide injection	Diagnostic renal imaging agent
Indium ( $^{111}\text{In}$ ) pentetereotide (OctreoScan)	Detection of primary sites and metastases of Gastro-entero-pancreatic endocrine tumors
Indium ( $^{111}\text{In}$ ) tropolonate white blood cells	Imaging infection and inflammation
Iodine ( $^{123}\text{I}$ ) Iobenguane (mIBG)	Diagnosis of neuroendocrine tumors
Iodinated ( $^{125}\text{I}$ ) albumin injection	Plasma volume studies
Sodium iodide ( $^{131}\text{I}$ ) injection and solution	Diagnosis and treatment of thyroid carcinoma
Thallous ( $^{201}\text{Tl}$ ) chloride injection	Myocardial visualization

generally produced in a 'hot cell' with a dedicated, automated synthesis unit.

Nonimaging diagnostic procedures are also used, for example, in kidney and hematological investigations. Longer-lived isotopes with half-lives of many days are used in these studies (e.g., chromium ( $^{51}\text{Cr}$ )).

Radiopharmaceuticals for use in therapy should have a long retention time and be highly selective. Low-energy beta emitting isotopes are used (e.g., iodine ( $^{131}\text{I}$ )). Some high-energy beta emitters (yttrium ( $^{90}\text{Y}$ ), phosphorus ( $^{32}\text{P}$ )) and alpha emitters (bismuth ( $^{213}\text{Bi}$ )) are also used.

The other main area of use for radiopharmaceuticals is as a research tool in drug formulation and drug delivery systems. For instance, molecular imaging using PET tracers can help in 'proof of concept' in drug development studies.

The radionuclides used in radiopharmaceuticals (Table 2) are produced by one of three methods. In cyclotron production a target material is bombarded with an ion beam and various isotopes are formed depending on the target material. Radionuclides can also be produced in nuclear reactors where nuclear fission leads to the production of a great number of radionuclides, some of which can be used *in vivo* after complex purification processes. Some radionuclides are produced from the decay of a radioactive parent. The parent generally has a longer half-life than the daughter radionuclide. In a generator system the parent is immobilized on an inert substrate and the daughter can be washed off ('eluted'). Technetium ( $^{99}\text{Tc}^{\text{m}}$ ) is produced by this method from the decay of molybdenum ( $^{99}\text{Mo}$ ).

**Table 2** Examples of radionuclides used in clinical practice

<i>Use</i>	<i>Radionuclide</i>	<i>Production method</i>	<i>Radiation emitted</i>	<i>Half-life</i>
Diagnostic (a) Imaging	$^{11}\text{C}$	Cyclotron	$\beta +$	20 min
	$^{13}\text{N}$	Cyclotron	$\beta +$	10 min
	$^{15}\text{O}$	Cyclotron	$\beta +$	2 min
	$^{18}\text{F}$	Cyclotron	$\beta +$	110 min
	$^{67}\text{Ga}$	Cyclotron	$\gamma$	78 h
	$^{81}\text{Kr}^{\text{m}}$	Generator	$\gamma$	13 s
	$^{99}\text{Tc}^{\text{m}}$	Generator	$\gamma$	6 h
	$^{111}\text{In}$	Cyclotron	$\gamma$	67 h
	$^{123}\text{I}$	Cyclotron	$\gamma$	13 h
	$^{133}\text{Xe}$	Nuclear reactor	$\beta - \gamma$	5.3 days
	$^{201}\text{Tl}$	Cyclotron	X-rays	73 h
	$^{51}\text{Cr}$	Nuclear reactor	$\gamma$	28 days
	$^{57}\text{Co}$	Nuclear reactor	$\gamma$	270 days
	$^{125}\text{I}$	Nuclear reactor	X-rays	60 days
Therapy	$^{32}\text{P}$	Nuclear reactor	$\beta -$	14 days
	$^{89}\text{Sr}$	Nuclear reactor	$\beta -$	52.7 days
	$^{90}\text{Y}$	Generator	$\beta -$	64 h
	$^{131}\text{I}$	Nuclear reactor	$\beta - \gamma$	8 days
	$^{213}\text{Bi}$	Generator	$\alpha$	46 min

Radiopharmaceuticals are usually formulated as sterile, pyrogen-free injections. There are exceptions, such as oral preparations, gaseous preparations, and the isotope generators themselves. While the preparation of radiopharmaceuticals is subject to the same regulations as any other pharmaceutical, due to the short half-life of many of the isotopes, products are often released for use before many of the quality control aspects can be completed. It is important that good manufacturing practice and good laboratory practice should be strictly followed. In the European Community, products bearing a product license number indicate that they have been approved for clinical use by the regulatory bodies and are termed 'licensed'. Unlicensed products may be used but responsibility for their efficacy rests with the individual clinician. Other countries, e.g., the USA, have similar regulations. Monographs listing the quality parameters for many radiopharmaceuticals are given in the Pharmacopoeiae and products supplied to patients must adhere strictly to these. The remainder of this article will outline the tests that should be carried out.

## Activity Check

There are very strict limits on the amount of radioactivity that can be administered for each type of investigation to be performed. These limits are set by the legislative bodies in individual countries. Therefore, all radioactive preparations must be checked for activity before administration. Most radionuclide calibrators used in radiopharmacy are ionization chambers. Commercial calibrators have built in scaling factors for individual radionuclides that take into account the ionizing ability of the isotope and give a readout in the appropriate units (kBq or MBq, or mCi). However, this type of calibrator is not ideal for all radionuclides. Low-energy radiation, such as that produced by iodine ( $^{125}\text{I}$ ), may be attenuated before reaching the gas and the measurement may be inaccurate. Also, high-energy beta particles interact with the chamber wall and the measurement of activity is based on the Bremsstrahlung radiation produced. The activities dispensed in a radiopharmacy need to be measured to a precision of 2–5%. It is very important that the radionuclide calibrator used is working correctly and a strict quality assurance regime should be followed to ensure this. The calibrator is checked daily for accuracy against a long-lived reference sealed source (e.g., cobalt ( $^{57}\text{Co}$ ) or americium ( $^{241}\text{Am}$ )), there should also be an annual linearity check. The accurate determination of low activities of X-ray and gamma-emitting radionuclides can be carried out using a well scintillation counter, in which a scintillant crystal produces a flash of light

when struck by an ionizing particle or photon. The light produced is converted to an electrical signal by a photomultiplier, which can then be amplified and counted. Gamma and X-rays are best detected with crystals of thallium-activated sodium iodide ( $\text{NaI(Tl)}$ ). In a well counter the source is placed inside a well drilled in the center of a cylindrical crystal. Liquid scintillation counting is used in the measurement of beta emitters, such as tritium ( $^3\text{H}$ ) and carbon ( $^{14}\text{C}$ ).

## Radionuclide Identity

A radionuclide can be identified by measuring the half-life of the radionuclide and/or determining the energies of the emitted radiation.

The half-life is measured with a suitable detector (see above). There must be sufficient activity in the sample so that it can be measured for several half-lives, but limited to minimize count rate defects and effects such as dead time losses. Multiple measurements are made in the same geometrical conditions, for a time at least equal to three expected half-lives. A graph is drawn with the logarithm of the instrument response against time. The half-life is calculated from the graph and should not differ by more than 5% from the half-life stated in the Pharmacopoeiae.

The nature and energy of the radiation emitted may be determined by several procedures depending on the type of radiation emitted. Radionuclides that emit gamma rays or detectable X-rays can be analyzed using gamma spectrometry. The spectrum can be used to identify which nuclides are present in a source and in what quantities. Nuclides that emit alpha and beta particles can be analyzed using liquid scintillation counting and spectrometry. Beta particle emitters can also be analyzed by the construction of an attenuation curve. The radiation source is placed in front of a Geiger–Mueller counter. The count rate is measured and a succession of aluminum sheets of increasing thicknesses are placed between the source and the counter and the measurement repeated. This is continued until there is no reduction in counts by the addition of more sheets. This procedure is repeated for a standard source. The mass attenuation ( $m_m$ ) can be calculated for the sample and standard using the following equation:

$$m_m = \frac{\ln A_1 - \ln A_2}{m_2 - m_1}$$

where  $m_1$  is the mass per unit area of the lightest screen,  $m_2$  the mass per unit area of the heaviest screen,  $A_1$  the count rate for mass per unit area  $m_1$ , and  $A_2$  the count rate for mass per unit area  $m_2$ .

The value obtained for the sample should not vary by more than 10% from the standard source.

## Radionuclidic Purity

This is the amount of radioactivity due to the radionuclide concerned compared to the measured activity of the radiopharmaceutical preparation. It is usually expressed as a percentage. The relevant monographs in the Pharmacopoeiae give limits to the radionuclidic impurities allowed in each preparation. If significant levels of other radionuclides are present then biological distribution may be altered. Radionuclide impurities can occur as a result of the manufacturing process, for example, for nuclides produced by cyclotron there can be contaminants due to impurities in the target or by the energy of the reaction. For example, yttrium ( $^{86}\text{Y}$ ), for use in PET, is produced by the reaction (p, n) on a target of strontium ( $^{86}\text{Sr}$ ) using protons with energy of 16 MeV. If energy of 30 MeV is used then yttrium ( $^{85}\text{Y}$ ) is also produced, which decays to strontium ( $^{85}\text{Sr}$ ). This radionuclide has a long half-life and targets bone, having serious implications for patients. Impurities can also arise due to the presence of the parent nuclide of the stated nuclide when the stated nuclide is obtained by a separation technique such as a generator elution, for example, the presence of molybdenum ( $^{99}\text{Mo}$ ) in a solution of technetium ( $^{99}\text{Tc}^{\text{m}}$ ). The presence of molybdenum ( $^{99}\text{Mo}$ ) in a technetium ( $^{99}\text{Tc}^{\text{m}}$ ) radiopharmaceutical would be detrimental for patients due to the beta emission of this radionuclide and the long half-life (66 h) giving an increased radiation dose.

The radionuclidic purity can be determined by gamma spectrometry, or by the determination of the half-life. The half-life method is only a qualitative assessment but is useful for very short lived isotopes for use in PET, such as oxygen ( $^{15}\text{O}$ ) (half-life 2 min).

A version of the attenuation method can be used to determine the amount of molybdenum ( $^{99}\text{Mo}$ ) in a solution of technetium ( $^{99}\text{Tc}^{\text{m}}$ ) as these two radionuclides emit gamma radiation of very different energies. The activity of the sample is determined in an ionization chamber on the technetium setting. The activity measured will be due to technetium ( $^{99}\text{Tc}^{\text{m}}$ ) and molybdenum ( $^{99}\text{Mo}$ ). The sample is then placed in a lead canister with wall thickness of 6 mm and measured again on the molybdenum setting. The radiation emitted by technetium ( $^{99}\text{Tc}^{\text{m}}$ ) has energy of 140 keV, which is absorbed by the lead. The radiation emitted by molybdenum ( $^{99}\text{Mo}$ ) has energy of 740 keV and is only attenuated by a third. Any measured activity is therefore due to the molybdenum ( $^{99}\text{Mo}$ ) present. The proportion of molybdenum in

the sample can then be calculated. The limit allowed is 0.1% contaminating molybdenum ( $^{99}\text{Mo}$ ). This test should be performed daily on the first elution from a generator.

Due to differences in the half-lives of the different radionuclides that can be present in a preparation, the radionuclidic purity changes with time. The requirement of the radionuclidic purity must be fulfilled throughout the period of validity.

## Radiochemical Purity Determination

It is important to know that the majority of the radioactive isotope is attached to the ligand and is not free or attached to another chemical entity as these forms may have a different biodistribution. This is termed the radiochemical purity (RCP). In diagnostic scanning the different biodistribution of contaminating radioactive chemicals could interfere with the clinical diagnosis by obscuring the region of interest and interfering with the interpretation of the scan. This could result in the patient returning to the department for a repeat scan with all the cost implications for the department and a repeat radiation dose for the patient, or, more seriously, to a misinterpretation of the images. Abnormal biodistribution can also be due to other causes such as patient medication; therefore, determining the RCP could help to clarify an abnormal scan by ruling out defective product. In radiopharmaceuticals used for therapy a low RCP could mean an unacceptable radiation dose to healthy organs and tissues.

For most radiopharmaceuticals the lower limit of RCP is 95%, that is, at least 95% of the radioactive isotope must be attached to the ligand. RCP determination can be carried out by a variety of chromatographic methods.

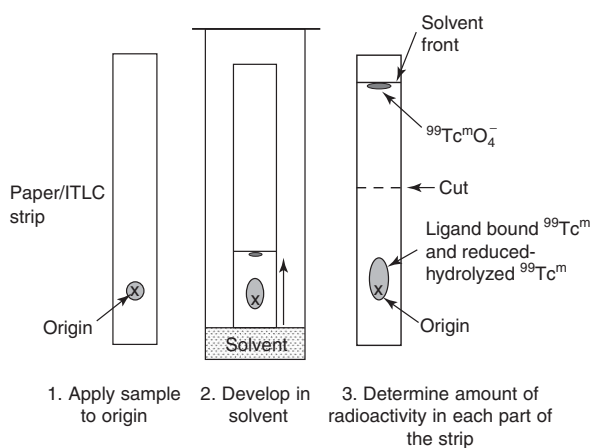

### Paper and Thin-Layer Chromatography

In these methods, a small drop of the radiopharmaceutical is put onto the bottom of a strip of support medium (e.g., paper, silica gel-coated sheets). The strip is put into a tank containing a small amount of solvent. The solvent migrates up the strip. The components of the radiopharmaceutical are separated according to the solubility in the solvent and adsorption to the support medium (Figure 1). Detection of the radioactivity in the strip can be carried out in a number of ways:

1. The simplest method is to cut the strip and count the activity in the sections in a radionuclide calibrator or a well scintillation counter. The percentage of activity in each section can then be determined. This method does have several limitations, however.

Radionuclide calibrators are inaccurate for samples of low activity due to the lower level of detectability and the accuracy of the calibrator at the lower range setting. Well scintillation counters should be avoided for samples of high activity, as these can exceed the count rate capabilities due to the resolving time of the detection system.

2. The strip can be imaged under a gamma camera. Regions of interest can be drawn around the areas of radioactivity and the percentage of counts in each region can be determined. This method has the advantage of imaging the whole chromatography strip enabling artifacts to be seen; however, it is not practicable for most hospital departments due to the cost of camera time.

**Figure 1** Determination of radiochemical purity by paper and instant thin-layer chromatography (ITLC).

3. The strip can be imaged using a radiochromatogram scanner. A radiochromatogram scanner uses a sodium iodide detector to detect the radioactive emission. If the scanner is linked to an integrator then quantification of the peaks can be carried out. This equipment is not suitable for counting emissions from some isotopes (e.g., chromium ( $^{51}\text{Cr}$ ) or iodine ( $^{125}\text{I}$ )) due to statistics associated with counting low activities.

4. Analysis of the strip can be performed using storage phosphor imaging. A phosphor screen accumulates a latent image of the distribution of radioactivity on the strip. Scanning the screen with a laser allows the location and intensity of radioactivity to be analyzed and stored for future reference. Results are shown as an image of the strip. Regions of interest can be drawn and integration carried out to determine activity in each region. **Figure 2** shows an image of a chromatogram of sodium chromate ( $^{51}\text{Cr}$ ) solution obtained using a phosphor imager. By varying the time of exposure of the strip to the phosphor screen, radiopharmaceuticals containing many different isotopes, or of different activities, can be analyzed.

One of the biggest drawbacks to paper and thin-layer chromatography (TLC) methods of determining RCP is the resolving power of the methods. Most methods commonly used will only resolve one component and so two or three methods may be needed to identify all the major contaminants in a product. Time can also be a limiting factor with some methods taking 20–30 min to develop, or even longer.

**Figure 2** Image of a chromatogram of sodium chromate ( $^{51}\text{Cr}$ ) solution obtained using a phosphor imager.

**Figure 3** Determination of radiochemical purity using solid-phase extraction.

### Solid-Phase Extraction

A variety of bonded silica sorbents are available packed into disposable cartridges or columns. The sorbent will selectively retain specific types of chemical compounds from the sample loaded on the column. There are many different sorbents available and many suppliers and manufacturers of solid-phase extraction (SPE) columns and cartridges. **Figure 3** shows a typical extraction procedure using SPE for radiopharmaceuticals. Components can be selectively eluted by careful choice of solvents. Eluates are collected and have sufficient activity that they can be counted in a radionuclide calibrator. The procedure takes ~5 min ensuring that RCP determination can be carried out before administration of the patient dose.

### High-Performance Liquid Chromatography

TLC RCP methods may not be sufficient to identify all the compounds that are present in a product. High-performance liquid chromatography (HPLC) has a higher sensitivity and resolving power than simple TLC methods. Gamma emitters are detected using a well scintillation counter connected to a rate meter. Other detectors (ultraviolet or refractive index) can be connected in series allowing simultaneous identification of compounds.

It should not be necessary to perform HPLC on radiopharmaceuticals reconstituted from licensed cold kits. It is useful to have techniques available for the purpose of eliminating a cause of any abnormal patient scan. For radiopharmaceuticals prepared 'in-house' or novel compounds for research purposes, an HPLC method for estimating RCP is essential. It should be noted that HPLC does not detect colloidal contaminants and that this should be estimated using TLC methods.

### Electrophoresis

Electrophoresis separates components in a sample according to the charge and size of the molecules. The most frequently used electrophoresis method in radiopharmacy is in the RCP determination of iodinated ( $^{125}\text{I}$ ) albumin injection. A drop of iodinated ( $^{125}\text{I}$ ) albumin injection containing at least 0.5 mg albumin is placed on a strip of filter paper ( $5 \times 30$  cm). Electrophoresis is carried out using barbitone-acetate buffer at 500 V for 1 h.

### Chemical Purity

Chemical purity requires the identification and quantification of individual chemical constituents or impurities in a radiopharmaceutical preparation. A routine test for chemical purity is performed on technetium ( $^{99}\text{Tc}^{\text{m}}$ ) sodium pertechnetate solution eluted from a generator. Technetium ( $^{99}\text{Tc}^{\text{m}}$ ) sodium pertechnetate solution may be contaminated with aluminum, which originates from the alumina bed of the generator column. The presence of aluminum can interfere with the preparation of some technetium ( $^{99}\text{Tc}^{\text{m}}$ ) colloidal preparations and also with the labeling of red blood cells with technetium ( $^{99}\text{Tc}^{\text{m}}$ ), causing their agglutination. The aluminum in the eluate can be detected using a simple paper test that is commercially available. Filter paper is impregnated with a color complexing agent. A standard solution of aluminum ( $10 \mu\text{g ml}^{-1}$ ) is supplied. A spot of the standard solution causes a color change in the paper. A spot of generator eluate is compared to the standard spot. If the color is more intense in the eluate spot then the eluate contains more than  $10 \mu\text{g ml}^{-1}$  aluminum and implies a lack of stability in the column; consequently the eluate should be discarded.

It should not be necessary to perform other chemical tests on licensed radiopharmaceuticals. Unlicensed radiopharmaceuticals should be checked for chemical purity to ensure the quality of the product. This would include the quantification of the normal constituents of a labeling kit, i.e., the ligand and reductant. Synthesis precursors or catalysts used in the preparation should be tested for. Commonly, this can be carried out using HPLC. Gas chromatography methods are used to test PET tracers for residual solvents used in the synthesis of these agents.

### Particle Sizing and Counting

Particulate radiopharmaceuticals rely on a specific particle size to be effective. For example, technetium ( $^{99}\text{Tc}^{\text{m}}$ )-macroaggregates of human serum albumin (MAA) (for use in lung imaging) have a particle size

range of 10–100  $\mu\text{m}$ . Particles in this particular size range are trapped in the pulmonary capillary bed, which can then be imaged. Smaller particles will not be trapped and will remain in circulation giving a high background, or will be filtered out by the reticuloendothelial system giving high counts in the liver and spleen. Larger particles will not enter the smallest capillaries and so the whole lung will not be imaged. The proportion of small particles in the preparation can be determined by filtration. The preparation is filtered through a 3  $\mu\text{m}$  polycarbonate filter unit. The eluate is collected and the activity in the eluate and on the filter is counted. Activity in the eluate is due to free technetium ( $^{99}\text{Tc}^{\text{m}}$ ) or particles less than 3  $\mu\text{m}$  in size. There should be less than 5% of the activity in the eluate. This method can also be used to determine the RCP of the product.

Particle size and number can be determined by light microscopy using a hemocytometer.

## Sterility Testing

Radiopharmaceuticals for parenteral administration should be sterile. Preparation under aseptic conditions should ensure this; however, conditions and operator dispensing technique can be checked by carrying out sterility testing of products.

Sterility testing of short-lived radiopharmaceuticals can be carried out by inoculating broth culture media with a small volume of the preparation (0.3 ml) under aseptic conditions. The broth can then be incubated, for about 2 weeks, and examined for growth. If the facilities are available this can be performed in the laboratory; however, this is not

possible for most hospital radiopharmacies. In this case the inoculated broths are stored at room temperature under suitable shielding until the radioactivity has decreased enough for the samples to be transported to a quality control testing laboratory. An alternative to this method is filtration of the sample under aseptic conditions using a 0.2  $\mu\text{m}$  filter. The filter is then cultured in the broths mentioned above.

The results of sterility testing are retrospective and are chiefly a control of quality of production.

## Pyrogenicity Testing

Bacterial endotoxins (pyrogens) are polysaccharides from bacterial membranes. They are water soluble, heat stable, and filterable. If they are present in a preparation and administered to a patient they can cause fever and also leukopenia in immunosuppressed patients. To minimize the chances that pyrogens are present it is important that preparations are manufactured and dispensed under aseptic conditions and that all consumables and equipment used have been heat treated and known to be pyrogen free. Most licensed products are guaranteed pyrogen free. However, the Pharmacopoeiae state that certain radiopharmaceutical preparations are required to comply with the test for pyrogens and it may be necessary to test for pyrogens in unlicensed products or intermediates used in manufacture. This test can either be performed in rabbits or a test for bacterial endotoxin employing limulus amoebocyte lysate may be used. These tests can be carried out in the radiopharmacy or by a quality control testing laboratory.

**Table 3** Quality control tests required for radiopharmaceuticals manufactured by different methods

<i>Test</i>	<i><math>^{99}\text{Tc}^{\text{m}}</math> radiopharmaceuticals from licensed kits</i>	<i>Ready-to-use licensed products</i>	<i>PET radiopharmaceuticals</i>	<i>Research and unlicensed products</i>
Activity check	Each dose	Each dose	Each dose	Each dose
Radionuclidic identity	No	No	Every batch	No
Radionuclidic purity	Daily – first generator eluate	No	Every batch	Every batch
Radiochemical purity	Monthly or new batch of cold kit	No	Every batch	Every batch
Chemical purity	First and last generator eluate only	No	Every batch	Every batch
Particle sizing and counting	$^{99}\text{Tc}^{\text{m}}$ -MAA at regular intervals	No	No	No (unless particulate)
Sterility	Weekly	No	At regular intervals	Every batch
Pyrogenicity	No	No	At regular intervals	Every batch
pH	No	No	Every batch	Every batch
Visual examination	Each dose	Each dose	Each dose	Each dose
Biodistribution	No	No	No	Every batch

## pH

The pH of the preparation should be in the physiologically acceptable range (5.5–8) or at the optimum pH for the stability of the preparation. It is especially important to check the pH of PET radiopharmaceuticals as preparative operating procedures may include extreme pH conditions that need neutralization. pH can be checked by placing a drop of solution on pH paper. Reading the paper is done by referring to a colorimetric pH scale. Micro-pH meters are available that can read a drop of liquid (10 µl) placed on the electrodes.

## Visual Examination

As with all pharmaceutical preparations, radiopharmaceuticals should undergo a visual examination. The examination should take into account radiation protection issues for the operator and be conducted as quickly as possible with the preparation behind suitable shielding. Vials should be examined for insecure closures, cracks, glass particles in the liquid, and particulate contamination. Syringes should also be examined for particulate contamination.

## Biodistribution

Checking the biodistribution of radiopharmaceuticals is not necessary with licensed products and is not usually undertaken in most hospitals; however, the monographs for some agents give requirements for biodistribution studies. In development work with new agents, studies into the biodistribution are essential. In biomedical research radiopharmaceuticals are used to determine the biodistribution of the 'cold' drug under study. Biodistribution of radiopharmaceuticals can be checked by injecting animals and imaging under dedicated cameras especially designed for such work. The animals can be killed and dissected at suitable time points and organs, blood, urine collected and counted and the

biodistribution determined. Whole body slices can be made and the distribution of radioactivity can be visualized using autoradiography. It should be noted that the biodistribution in animals (even other primates) can be very different from that obtained in humans.

It is not necessary to perform all of the above tests on every product. **Table 3** summarizes the number and frequency of testing required for products manufactured by different methods.

## Introduction

Raman spectroscopy is a powerful and versatile technique that is rapidly gaining popularity both in the laboratory and in the field. There are many variations of Raman spectroscopy including spontaneous Raman scattering, coherent anti-Stokes Raman scattering, Raman optical activity, hyper-Raman spectroscopy, and several types of Raman gain spectroscopy. Each of these has unique requirements for instrumentation. The simplest and most popular variation is spontaneous Raman scattering. The instruments used to measure spontaneous Raman scattering can be classified as filter instruments, dispersive spectrographs, or interferometers. This article describes filter instruments and dispersive spectrographs used for spontaneous Raman scattering.

Spontaneous Raman instruments illuminate a sample with monochromatic light and determine the intensities of new wavelengths of light created by the sample. Some important guiding principles for Raman instrument design can be drawn directly from the basic physics of Raman scattering. Raman scattering cross-sections are on the order of  $10^{-31} \text{ cm}^2$  molecule per steradian per, or  $\sim 15$  orders of magnitude smaller than those for fluorescence. A typical Raman sample will produce one Raman scattered photon from  $10^6$  to  $10^8$  excitation photons. Intense light sources and efficient collection of Raman photons are required in order for an adequate number of Raman photons to be detected. Even so, the number of Raman photons produced is usually small enough for measurements to be shot-noise limited, so the signal-to-noise ratio increases with the square root of the number of Raman photons detected.

The weak Raman signal is easily overwhelmed if more intense light from other sources reaches the

detector. Excitation light elastically scattered (no wavelength change) from the sample is orders of magnitude more intense than the Raman signal and must be severely attenuated. Vanishingly small intensity at the wrong wavelength contaminating the excitation light, if present, will elastically scatter from the sample and can severely distort the Raman spectrum. If the sample or impurities in the sample fluoresce, the fluorescence intensity can easily overwhelm the Raman spectrum. Even room lighting elastically scattered from the sample can distort or obscure the Raman spectrum.

Raman scattering intensity is inversely proportional to the fourth power of the emission wavelength. Decreasing the excitation wavelength, therefore, rapidly increases the Raman signal. Unfortunately, decreasing the excitation wavelength also increases the likelihood that intense fluorescence from the sample will obscure the Raman spectrum. Raman measurements are often made in the near-infrared spectral region despite the loss in sensitivity in order to avoid fluorescence. Very low excitation wavelengths, below  $\sim 250 \text{ nm}$ , largely avoid fluorescence because most fluorescence that does occur is outside the spectral region of the Raman spectrum. Sample absorption and photolytic damage become more of a problem at these short wavelengths.

The spectral range, in nanometers, needed to include the entire Raman spectrum decreases with decreasing excitation wavelength, as illustrated in **Figure 1**. For example, with  $800 \text{ nm}$  excitation, a  $4000 \text{ cm}^{-1}$  Raman spectrum extends to  $1176 \text{ nm}$ , a  $376 \text{ nm}$  spectral range. At  $200 \text{ nm}$ , the same  $4000 \text{ cm}^{-1}$  Raman spectrum extends to  $217 \text{ nm}$ , only a  $17 \text{ nm}$  spectral range. To maintain the same Raman spectral resolution in  $\text{cm}^{-1}$ , shorter excitation wavelengths require greater spectral resolution (expressed in nanometers) from the Raman instrument. A Raman spectral resolution of  $5\text{--}10 \text{ cm}^{-1}$  is often adequate for condensed-phase samples, but shifts as small as  $0.1 \text{ cm}^{-1}$  can sometimes be used to extract important chemical information.

The remainder of this article examines the main subsystems of a Raman instrument: the laser source, the sample interface, the spectrometer, and the

**Figure 1** Quantum efficiencies of Raman detectors shown with the Raman spectral regions for various lasers. Solid curves represent CCD detectors: 1, back-illuminated; 2, back-illuminated, deep depletion; 3, front-illuminated, deep depletion; 4, front-illuminated. Dashed curves represent photomultiplier tubes: 5, GaAs photocathode; 6, GaAsP photocathode; 7, multialkali photocathode. The solid lines at the top indicate the spectral region of a 0–4000  $\text{cm}^{-1}$  Raman spectrum excited with various laser wavelengths: a, 213 nm Nd:YAG fifth harmonic; b, 224.3 nm HeAg; c, 244 nm argon-ion second harmonic; d, 266 nm Nd:YAG fourth harmonic; e, 400 nm GaN; f, 488.0 nm argon-ion; g, 514.5 nm argon-ion; h, 532 nm Nd:YAG second harmonic; i, 632.8 nm HeNe; j, 647.4 nm krypton-ion; k, 752 nm krypton-ion; l, 785 nm stabilized diode. 3650  $\text{cm}^{-1}$  and higher is beyond 1100 nm; m, 850 nm stabilized diode. 2675  $\text{cm}^{-1}$  and higher is beyond 1100 nm.

detector. Special emphasis is placed on the sample interface because it is the primary differentiator between different Raman instruments. It is also the part of the Raman instrument that the user interacts with the most. The article concludes by considering the integration of these subsystems into Raman instruments for the research laboratory, for routine analysis, for process control, and for field-portable applications.

## Laser Sources

Lasers with adequate power for Raman spectroscopy are now available at nearly any wavelength from the vacuum ultraviolet to well into the near-infrared spectral region. Several important laser wavelengths are included in Figure 1. The laser power used for a typical Raman measurement tends to increase with increasing wavelength, both because laser-induced damage thresholds tend to be greater and Raman sensitivities tend to be lower at longer excitation wavelengths. For example, most Raman measurements can be made with a few milliwatts of average ultraviolet laser power, a few tens of milliwatts of visible laser power, and a few hundreds of milliwatts of laser power at 1064 nm. It is not uncommon,

though, to use much greater laser power in order to enhance sensitivity when the sample can tolerate it. Raman measurements in aqueous solution often use several hundred to a few thousand milliwatts of laser power. Samples, and even optical elements, are often less tolerant to pulsed lasers, especially low-repetition-rate short-pulse lasers.

Most lasers have a preferred, stable, linear polarization. Those that do not are a potential source of measurement artifacts. Raman spectra can change with changing polarization of the excitation source. A randomly polarized laser does not generally provide equal intensity for all polarizations as is frequently assumed. To the extent that the polarization of the excitation light reaching the sample is not controlled, the resulting Raman measurements may not be reproducible.

Atomic gas lasers used for Raman spectroscopy, such as argon-ion lasers and helium–neon lasers, have a narrow linewidth and a fixed frequency. Their spectral linewidth and frequency uncertainty have a negligible effect on most Raman spectra. The frequency of a solid-state laser is more affected by temperature and optical configuration, so must be determined experimentally. For example, a frequency-doubled Nd:YAG laser changes wavelength with changing temperature at a rate of 0.003 nm per  $^{\circ}\text{C}$ . Tunable solid-state lasers can have a much larger operating frequency range of tens to hundreds of nanometers.

The water-cooled argon-ion laser has been a favorite laser for laboratory Raman spectroscopy. It provides several green, blue, and near-ultraviolet laser lines with hundreds to thousands of milliwatts of optical power. The resulting Raman wavelengths are well matched to the optimum sensitivity of photomultiplier tube detectors. Air-cooled argon-ion lasers provide hundreds of milliwatts at 514.5 or 488.0 nm in a smaller, portable package at a lower cost. The water-cooled krypton-ion laser complements the water-cooled argon-ion laser with laser wavelengths in the near-infrared, red, and violet regions of the spectrum.

The 632.8 nm helium–neon (HeNe) laser is also very popular for Raman spectroscopy because it is small, portable, mature, and very inexpensive. The resulting Raman wavelengths are well matched to the optimum sensitivity of charge-coupled device (CCD) detectors. HeNe lasers used for Raman spectroscopy typically deliver 5–30 mW of optical power. Sometimes they also sporadically deliver a weaker laser-like beam at 650 nm that can cause a huge line in the Raman spectrum at 418  $\text{cm}^{-1}$ . The 650 nm radiation is due to an intracavity pumped laser Raman transition.

Diode lasers in the near-infrared, red, and, more recently, violet spectral regions are popular excitation sources for Raman spectroscopy. An individual diode laser can lase over a range of several nanometers, but when operated at low power, will often lase at a single narrow-band frequency. Careful control of the diode laser temperature and drive current, along with elimination of back reflections into the laser diode, can stabilize the lasing frequency long enough to collect high-quality Raman spectra. Most diode lasers used for Raman spectroscopy rely on external cavity stabilization (optical feedback at the desired wavelength) to maintain a constant laser frequency indefinitely. Diode lasers are available that operate in a single spatial mode. Light from these diode lasers can be focused to a diffraction-limited spot. Diode lasers are also available with a larger emitting surface in order to provide higher optical power, but these lasers, called broad-area laser diodes, cannot be focused as tightly.

Continuous-wave diode-pumped Nd:YAG lasers provide 1064 nm laser light for Fourier transform Raman (FT-Raman) instruments. They are often frequency doubled to provide 10–100 mW of 532 nm light for other types of Raman instruments. The weaker 1074 nm laser line sometimes lases at much lower intensity than the 1064 nm line. The resulting 537 nm light present in a 532 nm laser creates a large artifact band near  $175\text{ cm}^{-1}$  in the Raman spectrum. Over 10 000 mW of 532 nm light is available from standard larger lasers, however. Q-switched (pulsed) Nd:YAG lasers provide enormous peak optical power at 1064 nm that can be converted into many shorter wavelengths using various nonlinear optical techniques. The high peak power can easily damage samples, however.

The titanium-sapphire laser is perhaps the ultimate near-infrared laboratory laser for Raman spectroscopy. It is a continuous wave laser that can deliver thousands of milliwatts of laser light and is continuously tunable from below 700 to above 1000 nm. It provides a narrow bandwidth with a high-quality spatial mode. The spontaneous emission from the titanium-sapphire crystal must be filtered from the laser beam.

Most of the original deep-ultraviolet Raman spectroscopy relied on laser light derived from a Q-switched Nd:YAG laser. Fourth and fifth harmonic generation provided light at 266 and 213 nm, respectively. The combined use of optical harmonic generation and dye-laser pumping provided a laser system continuously tunable down to 217 nm. The use of a Raman shifter, or Raman laser, with the 266 nm fourth harmonic of the Nd:YAG laser produced wavelengths of 240, 218, and 199 nm. All of

the wavelengths derived from a Q-switched Nd:YAG laser had low average power and high peak power pulses, so samples could easily be damaged. The spatial beam quality was often poor, making it difficult to effectively deliver the optical power to the sample. More recently intracavity-frequency-doubling of water-cooled argon and krypton lasers has provided continuous-wave deep-ultraviolet power of tens to hundreds of milliwatts with excellent spatial beam quality at several discrete wavelengths. The most popular wavelengths are 257.2, 244.0, 229.0, and 203.4 nm. Hollow cathode ion lasers are a type of pseudocontinuous wave deep ultraviolet source for Raman spectroscopy. They are small, inexpensive, and rugged. They are essentially HeNe lasers with the neon replaced by silver or copper formed dynamically by sputtering. The HeAg laser produces a few milliwatts of 224.3 nm laser light and the NeCu laser produces several milliwatts of 248.6 nm laser light. They are operated in a pulsed mode, but their duty cycle is much higher than that of a Q-switched Nd:YAG laser so sample damage is much less likely.

Microchip lasers also need to be mentioned because they are likely to have a big impact on inexpensive portable Raman instruments in the future. A microchip laser consists of a thin plate (typically 0.3 mm thick) of laser gain material (usually Nd:YAG or Nd:YVO<sub>4</sub>) with laser mirrors deposited on both sides. Axial pumping creates a positive thermal lens that stabilizes the otherwise flat-flat laser cavity. The laser cavity is so short that only one longitudinal mode can lase, making the laser inherently very narrow band. Additional plates can be added between the mirrors for passive Q-switching (Cr:YAG plate) or intracavity frequency doubling. The most popular frequency doubling crystal for the generation of 532 nm light is KTP (potassium titanyl phosphate, KTiOPO<sub>4</sub>). Potassium niobate, KNbO<sub>3</sub>, is commonly used to generate 473 nm light. Passively Q-switched microchip lasers can generate a wide range of wavelengths using harmonic generation and optical parametric oscillation. They can be mass-produced inexpensively using wafer bonding and cutting technology developed in the semiconductor industry. A Q-switched, frequency doubled microchip laser, complete with its pump laser, can occupy less than 1 cm<sup>3</sup> of volume.

## Spectrometers

The Raman spectrometer filters out the unwanted laser light and delivers the proper Raman wavelengths to the proper detector(s). Once most of the laser light has been removed, the Raman light can be

processed using either a monochromator or a spectrograph. A monochromator transmits a desired Raman wavelength to the detector and rejects all the rest of the Raman photons. Spectrographs direct different Raman wavelengths to different detector elements. Spectrographs make much better use of Raman photons from the sample, but tend to have poorer stray light performance than monochromators. Good laser line rejection filtering minimizes the importance of spectrograph stray light performance, making spectrographs preferable to monochromators in most cases.

### Laser Line Rejection Filters

The best filter commonly used with a Raman spectrograph for rejecting the laser light without rejecting low-frequency Raman photons is a zero dispersion double spectrograph. This filter separates the different wavelengths of light spatially, removes the laser frequency, and puts the remaining wavelengths back together at its exit slit, as shown in **Figure 2**. A zero dispersion double spectrograph is a tunable filter. The laser rejection wavelength can be changed by simply moving the diffraction gratings. The zero dispersion spectrograph is complex and typically has a relatively low transmission of  $\sim 10\%$ .

Single element laser line rejection filters reject more of the low-frequency Raman spectrum, but

they tend to have a higher transmission, are simpler to set up and maintain, and are less expensive than a zero-dispersion spectrograph. The most common single element laser line rejection filters are thin-film interference filters, volume holographic filters, and rugate filters. Of the three, volume holographic filters provide the best laser line attenuation and least distortion of the Raman spectrum. Thin film interference filters are the least expensive. All three single element filters can be tuned over a limited wavelength range by tilting relative to the optic axis. Tilting causes the filter to have different transmission spectra for the two polarizations of light, which degrades the performance of the filter. Tilt angles greater than  $10^\circ$  are generally not recommended. As a result, a different single element laser line rejection filter is usually needed for each laser wavelength.

### Raman Monochromators

A Raman monochromator can be a diffraction grating instrument, two or three diffraction grating instruments in series (double or triple monochromator), or a single element bandpass filter. A triple monochromator is an extremely flexible instrument, but it is very complex and it uses Raman photons very inefficiently. All Raman photons outside the monochromator pass-band are lost. The first two monochromators serve as an excellent laser line rejection filter, though.

A thin film interference bandpass filter is often the monochromator of choice for simple gas-phase samples where low spectral resolution is acceptable. It is simple, inexpensive, and usually has high transmission. Multiple filters are often used together with multiple detectors in order to measure several Raman spectral regions simultaneously. Since the passband of a thin film interference filter shifts to shorter wavelengths with increasing angle of incidence, it is even possible to collect a full Raman spectrum by sequentially using a combination of tilt angles from different interference filters under computer control.

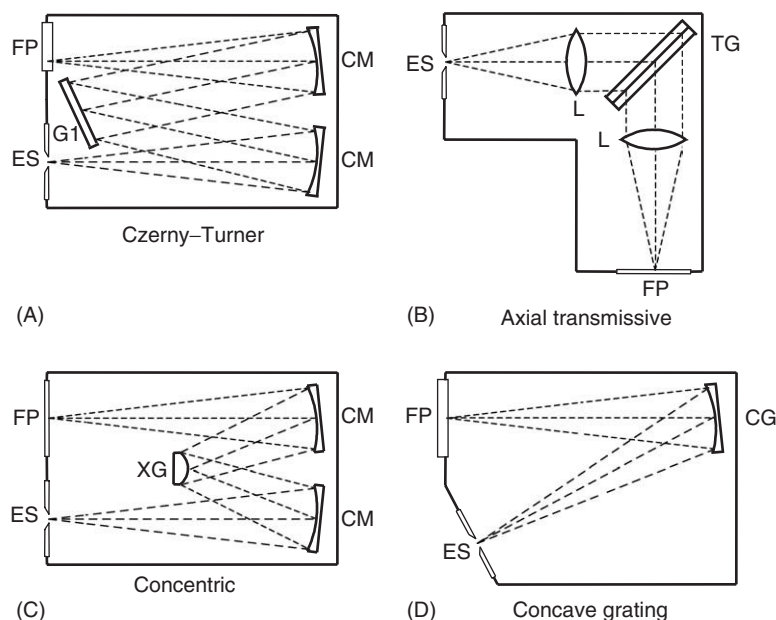

Tunable single element bandpass filters have also been used as Raman monochromators. The most popular are acousto-optic tunable filters and liquid crystal tunable filters. These filters are electrically tunable and are well suited to Raman imaging.

**Figure 2** Zero dispersion double spectrograph as a laser line wavelength rejection filter. Light passes through entrance slit S1 and forms a dispersed image at intermediate slit 2. Slit 2 is very wide and passes much of the spectrum, but not the laser wavelength. Grating G2 reverses the dispersion of grating G1 and focusing mirror M6 brings all the wavelengths back together at exit slit S3. M1, M2, M3, and M4 are concave mirrors. M3 and M4 are flat mirrors.

### Raman Spectrographs

Most modern laboratory Raman instruments use spectrographs with multielement detectors. **Figures 3** and **4** show optical diagrams of the more important spectrographs used for Raman spectroscopy. The Czerny–Turner spectrograph and its many variants are the most popular. Concave grating spectrographs

**Figure 3** One-dimensional spectrographs used for Raman spectroscopy. Several variations on these designs are available. FP, spectrograph exit focal plane; ES, entrance slit; CM, concave mirror; TG, transmission diffraction grating; L, multielement lens; XG, convex diffraction grating; CG, concave diffraction grating.

are advantageous for deep-ultraviolet work since there is only one optical element between the entrance slit and the detector. Off-axis imaging between the entrance slit and the detector for both the Czerny-Turner and the concave grating spectrograph degrades rapidly with decreasing  $f$ -number. A low  $f$ -number is often desirable, though, in order to maximize the Raman light intensity that can be delivered to the detector from a large sample area or optical fiber. Excellent imaging can be maintained at low  $f$ -number by replacing the concave mirrors of the Czerny-Turner spectrograph with multielement lenses. The stray light performance of the lenses is vastly inferior to that of mirrors, but is acceptable if a good laser line rejection filter precedes the spectrograph. Replacing the reflection grating with a transmission grating allows compact positioning of the optics with minimal vignetting. The result of these changes is the axial transmissive spectrograph shown in Figure 3. Concentric spectrographs are another approach to improve the imaging performance of a Czerny-Turner spectrograph at low  $f$ -number. They use a convex diffraction grating in a concentric configuration to correct optical aberrations.

Two-dimensional detectors provide the opportunity to divide a Raman spectrum into segments that can be stacked on top of each other at the detector, thereby increasing the spectral resolution for a given spectral range. Figure 4 shows two different ways to implement this concept. Raman instruments based

on echelle spectrographs and holoplex diffraction gratings are commercially available.

Optical elements not at normal incidence to both incoming and outgoing light generally have different properties for horizontally and vertically polarized light. As a result, spectrographs, monochromators, and even simple filters have a polarization-dependent transmission that can distort Raman spectra. Most Raman instruments provide a means to make the polarization of light entering the spectrograph independent of the polarization of the Raman photons from the sample in order to eliminate these distortions. One long-established way to do this is to use a stepped birefringent wedge (polarization scrambler) in the collimated space of the collection optics just prior to the spectrograph entrance slit.

## Sample Interface

The sample interface brings together the laser illumination and the spectrometer field of view at the desired location on the sample. The three most common sample interfaces are a sample compartment, a fiber optic probe, and a Raman microscope. Common to all three interfaces are the needs to condition the laser beam that illuminates the sample and to collect light from the sample.

Laser illumination usually needs to be spectrally filtered and focused before it reaches the sample. Spectral filtering removes plasma lines, spontaneous

**Figure 4** Two-dimensional spectrographs used for Raman spectroscopy. (A) combination of a filter spectrograph and a diffraction spectrograph. F1, F2, and F3 are dichroic beam splitters; G1 is a diffraction grating; L1 is a camera lens; FP is the exit focal plane. (B) Echelle spectrograph for Raman spectrometry. ES is the entrance slit; L1, L2 are camera lenses; G1 is a diffraction grating; G2 is an echelle diffraction grating; FP is the exit focal plane. A two-dimensional spectrograph can also be made by using a holoplex transmission grating in the axial transmissive spectrograph shown in **Figure 3**.

fluorescence from the laser gain medium, or other unwanted light generated by the laser. Focusing the laser on the sample reduces the size of the Raman emitting object that must be imaged through the spectrometer. Raman emitting surfaces larger than 50 to 100  $\mu\text{m}$  place much greater demands on collection optics and spectrometers, and usually increase the size and cost of the spectrometer optics. Laser beams focused directly on the sample are usually 1–50  $\mu\text{m}$  in diameter. The resulting optical power density is high enough to sometimes cause excessive sample heating at that spot and even sample damage. Optical power density can be reduced without loss of sensitivity by illuminating the entire region of the sample that is imaged through the spectrometer entrance slit.

**Figure 5** Relationships between  $f$ -number, numerical aperture (NA), and solid angle. The variable  $n_0$  is the refractive index of the medium.

The collection optics image light from the sample onto the spectrometer entrance slit. The solid angle of light from a point on the sample to the collection optic surface is often expressed as an  $f$ -number ( $f\#$ ), a numerical aperture (NA), or a solid angle (steradians). The relationship between these is illustrated in **Figure 5**. Increasing the solid angle of collection delivers more Raman photons to the spectrometer entrance slit, but increases the magnification of the sample image at the slit as well. The magnification of the collection optics must be low enough for the image of the illuminated region on the sample to be transmitted by the spectrometer slit, and the solid angle of the light reaching the spectrometer slit must be equal to or less than that of the spectrometer collection optic. Otherwise, some of the light collected from the sample will be blocked from the detector by the spectrometer.

Two other important aspects of the collection optics are standoff and depth-of-field. Standoff is the distance between the sample and the collection optic. The standoff distance is often critical for noncontact analysis. Standoff distances can be increased without reducing collection efficiency by increasing the size of the collection optics. Depth-of-field is a measure of how far the sample can be from the focal plane of the collection optics without a substantial loss of Raman intensity at the detector. Increasing the solid angle of collection reduces the depth-of-field.

Raman collection geometry refers to the angular relationship between the exciting light and the Raman scattered light. The two most common collection geometries,  $90^\circ$  and  $180^\circ$  backscattering, are illustrated in **Figure 6**. The  $180^\circ$  backscattering collection geometry is the most popular largely because the alignment between the excitation and collection paths is built into the collection optics, greatly simplifying alignment of the sample to the Raman instrument.

(A) 180° Backscattering geometry

(B) 90° Scattering geometry

**Figure 6** Raman measurement geometries. The solid line represents laser light and the dashed line represents Raman scattered light from the sample. Laser light and Raman light overlap between the beam splitter and the sample in 180° backscattering.

### Sample Compartment

The sample compartment is the traditional and most flexible sample interface for a Raman instrument. The sample is usually mounted on a three-axis translation stage, sometime with additional rotational adjustments. The sample movements can be either manual or computer controlled. A computer-controlled translation stage is often used as an autosampler. Multiple samples are loaded into an array of containers, such as a 96-well plate, and each sample is moved to the observation region and analyzed without human intervention. Sometimes the sample is moved by spinning, translating, or flowing during the acquisition of the Raman spectrum in order to minimize sample damage or to average out sample heterogeneity. The sample compartment also provides a controlled environment for the sample. It excludes room light and sometimes controls temperature and humidity. The sample compartment is usually large enough to contain experiments to be

**Figure 7** Nonfocusing fiber optic Raman probe. The sample is placed in the region where the excitation and collection paths overlap: (A) illustrates the overlap for a nonfocusing probe having a single excitation fiber and a single collection fiber; (B) illustrates a common configuration using a single excitation fiber and multiple collection fibers.

monitored with Raman spectroscopy such as an electrochemical cell, a reo-optical modulator, or a microchemical reactor.

### Fiber Optic Probes

Fiber optic probes have expanded the utility of Raman spectroscopy by taking the Raman measurement capability to the sample rather than requiring the sample to come to the Raman instrument. An optical fiber is used to deliver laser light to the remote sample and a separate optical fiber or bundle of fibers sends Raman photons back to the Raman instrument. Laser light in the optical fiber generates Raman and fluorescence that, if not removed, can contaminate the Raman spectrum of the sample. Most Raman probes use optical filters to remove Raman and fluorescence generated in the optical fiber. These filters are not always necessary when short lengths of optical fiber are used due to the weakness of the fiber emission, or when samples are transparent because the unwanted light is not scattered into the collection fiber. There are two main classes of fiber optic Raman probes for examining single points on a sample: focusing probes and nonfocusing probes.

**Figure 7** illustrates a nonfocusing fiber optic Raman probe. Diverging laser light from the delivery fiber illuminates the sample. Adjacent optical fibers collect light scattered back from the sample and deliver the light to the spectrometer. The collection

fibers are stacked on top of each other at the spectrometer to optimize coupling to the entrance slit. No single collection fiber collects light very efficiently from any specific point on the sample, but the total amount of Raman light collected by all of the collection fibers is often competitive with more traditional focused collection. Optical filters can be deposited on the ends of the individual optical fibers, or spliced into the fibers a short distance from the sampling end to minimize the impact of laser-induced emission from the optical fibers themselves on the Raman spectrum from the sample. When the relative positions of the collection fibers are tracked or preserved, a Raman image of the sample can be obtained. Fiber optic analogs of line and global imaging (see Raman microscope below) can be produced this way.

Figure 8 illustrates a focusing fiber optic Raman probe. Light from the laser delivery fiber is sent through a miniature monochromator inside the probehead before being focused onto the sample. Light from the sample is filtered to remove laser light and then injected into the collection fiber for return

**Figure 8** Schematic drawing of a focusing fiber optic Raman probehead. An internal micro-monochromator eliminates unwanted light from the excitation and a notch filter removes laser light from the Raman signal. A second notch filter acts as a dichroic filter to overlap the excitation and collection paths.

to the Raman instrument. Only a small region on the sample is illuminated and light from that region is collected efficiently. The sampling lens on the probehead that both focuses the laser light on the sample and collects light from the sample can be changed to meet the needs of a particular application. The most commonly changed lens parameters are stand-off from the sample and  $f$ -number. The separation between the probehead and the sampling lens is typically small, but can be many meters since the light between the two is collimated. As a result, the sampling lens can be located in a location incompatible with the probehead without loss in sensitivity. The alignment tolerance between the probehead and the sampling lens is very forgiving.

Table 1 compares the nonfocusing and the focusing fiber optic Raman probes. Both styles of probe have unique and important roles to play in fiber optic Raman spectroscopy.

### Raman Microscope

The first two Raman instruments that incorporated microscopes were reported in 1974. These were Raman microprobes, or Raman microspectrometers, because they acquired Raman spectra from microscopic sample volumes. One of these also provided for Raman imaging. The microscope enables these capabilities because its objective can focus a laser beam into a few-cubic-micrometer spot and collect scattered Raman photons through a wide angle. The percentage of Raman light collected is about three times higher for a high-efficiency nonimmersion objective than for a camera lens. In addition, a microscope's magnified optical image of the sample

**Table 1** Comparison of focusing and nonfocusing fiber optic Raman probes

<i>Focusing Raman probe</i>	<i>Nonfocusing Raman probe</i>
Can collect polarized spectra	Cannot collect polarized spectra
Spot size on sample 0.001–0.1 mm	Spot size on sample 0.5–5 mm
Interchangeable optics	Light managed by tip shape
Strong laser rejection	Little, if any laser rejection
No silica Raman artifacts	Silica Raman artifacts possible
Uses two small diameter fibers	Uses several larger diameter fibers
Large probehead	Probehead can be < 1 mm diameter
Requires larger access port	OK for long, narrow openings
\$5000–10 000	Simplest probes <\$1000
Poor utilization of slit height	Good utilization of slit height
Many probes to one analyzer	One or two probes to one analyzer

**Figure 9** A basic Raman microprobe couples laser light onto the sample through a beam splitter (A) and a microscope objective (B). Raman photons are collected with the same objective, so retrace the path to the beam splitter (A), where they continue on to mirror (C), which directs the Raman light into a spectrometer and ultimately to a CCD detector. The mirror (C) can be moved out of the path to allow a magnified view of the sample using a TV camera.

allows the operator to position the laser beam on the sample with respect to features such as heterogeneity, inclusions, domain boundaries, layers, or contamination. **Figure 9** illustrates the basic design of a Raman microprobe.

Confocal scanning optical microscopy, developed in the 1960s, offered significantly improved spatial resolution and contrast over those available using conventional microscopes. Though the application of this technique to Raman microscopy was originally difficult, it has since become a central design element of many current Raman microprobes. Advances in wavelength-filtering technology, the sensitivity of modern CCD detectors, and holistically designed and optimized systems have overcome most of the early problems. In a confocal design, light from a diffraction-limited spot focused on the sample is collected and refocused to a tiny image. A pinhole is placed to allow light passing through this image to reach the detector. Most of the light rays that originate outside of the focused sample spot are blocked, as shown in **Figure 10**. A confocal Raman instrument can have 1- or 2- $\mu\text{m}$  spatial resolution in all three dimensions. This is a powerful technique for discriminating against background scatter or fluorescence and for probing below the surface of a nonopaque sample. Caution must be exercised, however, when interpreting the axial distances involved, due to the

**Figure 10** A confocal aperture combined with the strong divergence of tightly focused light yields fine axial (depth) resolution. Light from a point source (such as a focused laser beam) is focused by a lens (microscope objective) to a small spot on a thin sample in (A). Raman-scattered light from the spot is re-imaged by the lens into the confocal aperture. However, if the sample is positioned below the focal plane of the lens, as in (B), the sample spot becomes larger and no longer forms an image in the confocal aperture. Rather, a larger image forms in front of the aperture. Most of the rays from the image in (B) are blocked from reaching the detector since they no longer line up with the opening.

focal position distortion that occurs when light rays cross boundaries between materials that have very different refractive indices.

Raman imaging captures contrast, similar to that in a photograph, originating from the spatial distribution of Raman spectral features in the sample. Spectral features can express such properties as molecular composition, stress, and degree of crystallinity, among others. Three main approaches have been taken to Raman imaging: point mapping, line imaging, and global (widefield) imaging. In point mapping, a Raman spectrum is collected from each spatial point sequentially, so the number of spectral acquisitions is equal to the number of image pixels. Global imaging collects the whole image at once for a single spectral element, so the number of image acquisitions is equal to the number of Raman spectral elements in the spectrum. Line imaging is a hybrid of the two approaches: spectra from a spatial line on the sample are collected simultaneously to make a line image. Multiple line images can be collected and combined to form a two-dimensional image. So, for a square image, the number of line acquisitions is equal to the square root of the number of image pixels. Each of these approaches has strong and weak points, as summarized in **Table 2**. Point mapping is very slow, but is the most easily implemented with common Raman systems and can be adapted to solve many sample problems. Global

**Table 2** Comparison of Raman imaging strategies

	<i>Point mapping</i>	<i>Line imaging</i>	<i>Global imaging</i>
Spectral resolution ( $\text{cm}^{-1}$ )	1	1	10
Spectral acquisition speed	Seconds	Seconds to minutes	Minutes
Usually collect continuous spectra	Yes	Yes	No
Definition of image	Low	Moderate	High
Image acquisition speed	Hours to days	Seconds to minutes	Seconds
Raman photons used per acquisition	Most	Most	Fewer
Laser power required	Low	Moderate	High
Confocal axial resolution	Yes	Sometimes	No
Robust to different surface geometries	More	More	Less
Moving sample and/or optics required	Yes	Yes	No

imaging has somewhat lower spectral resolution, but can provide the fastest and highest definition images. Line imaging uses CCD area the most efficiently since the line is imaged vertically on the detector pixels, while the spectra are dispersed horizontally.

## Detectors

Photomultiplier tubes and CCD detectors are the dominant detectors for Raman spectroscopy. Less common detectors include avalanche photodiodes for specialized applications in the near-infrared, single element photovoltaic detectors such as germanium or InGaAs detectors for FT-Raman measurements, and single element silicon photovoltaic detectors for stimulated Raman measurements.

### Photomultiplier Tubes

A photomultiplier tube (PMT) consists of a photocathode followed by an electron multiplier. A single photon ejects an electron from the photocathode. Electric fields in the PMT accelerate the electron into another surface called a dinode. The collision of the electron with the dinode releases several new electrons, which are accelerated into another dinode.

This process is repeated several times producing a typical electron gain of  $\sim 10^6$ . The current from the PMT can be measured directly, but better signal-to-noise ratio can be obtained using a nonlinear process called photon counting.

At low enough optical intensities (less than  $10^7$  photons per second) each photon produces a discrete current pulse from the PMT. If the gain of the PMT is  $10^6$  then current pulses from the PMT consisting of significantly less than  $10^6$  electrons are noise and can be ignored. Current pulses of  $\sim 10^6$  electrons are counted. The sum of the counts for a given period of time is proportional to the detected optical intensity. The probability that more than one photoelectron is produced simultaneously is negligible at low count rates, but causes nonlinearity between the optical intensity and count rate at higher optical intensities. Multilevel discriminators can extend the linear range somewhat by classifying pulses as zero, one, or two photons.

PMTs have a relatively large detection area making them well suited to most monochromators. Their dark noise per unit detection area is the lowest of any detector (lower than even cryogenically cooled CCDs). Their quantum efficiencies are in the range of 1–40% in the ultraviolet and visible spectral regions, but fall off rapidly in the near-infrared. PMTs have nanosecond response times that are useful for time-resolved Raman measurements.

### CCD Detectors

CCD detectors are the most popular detectors for Raman spectroscopy. CCD detectors consist of a two-dimensional array of silicon photovoltaic detectors and the associated electronics to read the signal from each detector element. Photoelectrons are stored at each detector element until a read operation removes them for measurement. The detector elements in CCD detectors commonly used for Raman spectroscopy are  $13\text{--}27\mu\text{m}^2$  on edge and are arranged as arrays of  $200 \times 200$  detector elements up to  $2048 \times 1024$  detector elements. CCD detectors with more detector elements are available, but offer diminishing returns for much greater expense. The electrons from multiple detector elements are usually combined to give the signal at any particular Raman wavelength because the spectrograph slit image is almost always much larger than an individual detector element. Raman imaging instruments may use all the detector elements separately, however, to maximize spatial resolution.

Typical quantum efficiencies for CCD detectors range from 30% to  $\sim 100\%$ . Quantum efficiencies fall off with wavelength as the silicon band gap at

1100 nm is approached, but greater than 20% quantum efficiency is possible at 1050 nm with optimized detectors. Quantum efficiency versus wavelength curves for some popular CCD detectors are shown in **Figure 1**. CCD detectors are normally cooled to  $-40^{\circ}\text{C}$  to  $-120^{\circ}\text{C}$  in order to reduce dark noise. Dark noise is reduced by a factor of 2 for each  $8\text{--}10^{\circ}\text{C}$  decrease in temperature. Dark noise can be reduced to less than one photoelectron per hour per detector element (20 photoelectrons per second per square centimeter of detector area), but this level of dark noise reduction is usually not necessary. Shot noise is usually the dominant noise in Raman spectra measured with a CCD detector.

## Integrated Instrumentation

An integrated Raman instrument is a single package containing the laser source, sample interface, spectrometer, detector, and computer all working in harmony together. Different Raman instruments can be compared based on performance factors such as sensitivity, detector noise, spectral resolution, spectral range, spatial resolution, and acquisition speed. They can also be compared on the basis of operational parameters such as size, cost, power consumption, and adaptability, or on the basis of application-specific factors such as laser wavelength, laser power, sample interface, and user interface. Several different types of Raman instruments are in common use because an optimal compromise of these parameters differs widely among Raman applications and vendors.

Integrated Raman systems can be classified as instruments designed for the research laboratory, for routine analysis, for process control, and for portable, field-deployable applications. Research laboratory instruments offer new and state-of-the-art capabilities in exchange for compromised reliability and frequent need for support from a Raman expert. Research laboratory instruments are extremely adaptable to address unanticipated measurement needs. Routine analysis instruments provide limited flexibility with good reliability. They are operationally simple and contain enough Raman expertise built in for technicians to carry out repetitive assays efficiently and reliably. Process control instruments are typically fiber optic Raman systems that have been hardened to perform in the more challenging environmental conditions typical of a chemical production facility. A process control instrument usually runs continuously in a fully automated mode. There

are usually no Raman experts available at the plant to calibrate, reoptimize alignment, or restart the instrument. Any instrument downtime can be very expensive and even dangerous. Process Raman measurements are often made under adverse temperature, vibration, chemical exposure, and pressure conditions. Field-portable Raman instruments are still at a low level of maturity. Size, weight, and utility requirements currently take priority over Raman performance.

## Glossary

Steradian	The SI unit of solid angle. There are $4\pi$ steradians in a sphere.
Shot noise	Fundamental noise due to the statistical nature of light. One standard deviation of the average intensity equals the square root of the total number of photons measured.
Monochromatic	Light having a spectrally narrow bandwidth.
Q-switched	Technique for generating short, intense laser pulses.
Polarization	Direction of the electric field vector in a beam of light.
Quantum efficiency	Ratio of photoelectrons to total number of incident photons absorbed by a detector.

### Introduction

When radiation passes through a transparent medium, the species present scatter a fraction of the beam in all directions. C.V. Raman discovered that incident light is inelastically scattered from a sample and shifted in frequency by the energy of its characteristic molecular vibrations, a phenomenon known as Raman scattering. Today, laser photons over a wide range of frequencies from the near-ultraviolet (near-UV) to the near-infrared (NIR) region are used in Raman scattering studies. By choosing wavelengths which excite appropriate electronic transitions, resonance Raman studies of selected components of a sample or parts of a molecule can be performed.

Over the past few years, the range of excitation wavelengths has been extended to the NIR region in which background fluorescence is reduced and photoinduced degradation of the sample is diminished. The NIR region of the spectrum extends from the upper wavelength end of the visible region at  $\sim 770\text{--}2500\text{ nm}$  ( $13\,000\text{--}4000\text{ cm}^{-1}$ ). For many years, NIR excitation of Raman spectra was not considered viable. However, now high-intensity NIR diode lasers are easily available, making this region attractive for compact, low cost Raman instrumentation. Furthermore, the development of low noise, high quantum efficiency, multichannel detectors (charge coupled device (CCD) arrays) combined with high-throughput single-stage spectrographs used in combination with holographic laser rejection filters, have led to high-sensitivity Raman spectrometers.

Classical, spontaneous Raman scattering is a powerful analytical tool that allows for the investigation of the qualitative and quantitative composition of biological, pharmaceutical, and environmental samples. The following discussion of NIR-Raman spectroscopy will begin with a general review of Raman spectroscopy, followed by a description of NIR-Raman, with further discussion about instrumentation and applications of the NIR-Raman technique.

### General Aspects of Raman Spectroscopy

When a beam of monochromatic light is incident on a sample, some of the light is transmitted, some is

absorbed, and some is scattered. Most of the scattered light has the same wavelength as the incident light, an effect known as Rayleigh scattering. However, a small fraction of the scattered light ( $\sim 1$  out of  $10^8$  photons) is shifted in wavelength, resulting in inelastic scattering or Raman scattering. In the Raman scattering, the differences in energy between the incident and the scattered photons are quantized, corresponding to the energy differences within the vibrational or the rotational levels of the molecules.

In Raman spectroscopy, the wavelength shift is defined as the difference in wavenumber,  $\Delta\nu$ , ( $\text{cm}^{-1}$ ) between the observed radiation and that of the source. Two types of Raman scattering are present, Stokes and anti-Stokes lines. Stokes lines are found at wavenumbers that are lower than the Rayleigh peak while anti-Stokes peaks occur at wavenumbers greater than the wavenumber of the laser excitation source. Anti-Stokes lines are generally considerably less intense than the corresponding Stokes lines. Fluorescence may seriously interfere with the observation of Stokes shifts but not with anti-Stokes, thus with fluorescing samples, anti-Stokes signals may sometimes be more useful despite their lower intensities. With highly fluorescing samples, it is more common to use a different excitation source, circumventing the production of fluorescence. This strategy frequently involves moving from the use of a visible laser source as an excitation source to one lasing in the NIR region.

**Figure 1** depicts an energy-level diagram showing the sources of Raman and Rayleigh scattering. When a photon having energy  $\nu_0$  collides with a molecule, two different events can take place. If the scattered photon has the same energy as the exciting photon, the Rayleigh scattering can be observed. The middle arrow depicts the changes that produce Rayleigh scattering. No energy is lost in Rayleigh scattering, thus the collisions between the photons and the molecule are termed elastic.

The energy changes that produce Stokes and anti-Stokes emission are depicted on the left and right, respectively. The two differ from the Rayleigh radiation by frequencies corresponding to  $\pm\Delta\nu$ , the energy difference between the first vibrational level and the ground state. In Stokes scattering, the molecule loses energy  $-\Delta\nu$ , reaching the vibrational level  $\nu=1$  and not returning to its vibrational state  $\nu=0$ . In this case, the scattered photon has energy  $\nu_0 - \nu_1$ , where  $\nu_1$  is the frequency of the vibration. In anti-Stokes scattering, the molecule originally in the

**Figure 1** Energy level schematic of Raman spectroscopy.

$v = 1$  state, is first promoted to a virtual excited state, then successively returns to the ground vibrational state,  $v = 0$ . The energy of the scattered photon is  $\nu_0 + \nu_1$  and the spectral line is shifted to a lower wavelength and a higher frequency than the incident radiation. However, since the majority of the molecules are in the ground vibrational state at room temperature, the Stokes lines is stronger compared to the anti-Stokes lines.

## NIR-Raman Spectroscopy

### The Difference in Excitation

Many books on Raman spectroscopy were written before NIR lasers became a viable excitation source. Traditionally, the relative magnitude of Raman spectroscopy is explained using the  $\nu^4$  factor, which indicates that the Raman intensity for normal Raman scattering varies with the fourth power of the observed frequency, an event dependent on the excitation laser frequency. However, since Raman is too weak to be seen by the naked eye without the aid of filters, it is difficult to find good analogies for teaching. The  $\nu^4$  process provides the explanation for several common phenomena, the blue sky and red sunset. Rayleigh proved that elastic scattering of light (Rayleigh scattering) is responsible for the blue sky. When the sky is observed during the day, the vision is overwhelmed by light scattered by atmospheric molecules. Since high frequencies scatter more and blue light is the highest frequency of the visible spectrum, the sky appears blue. At sunset just the opposite occurs and all the high frequencies are scattered away to the west. Thus, only the low frequencies of red and

orange are visible. Raman may be considered in this context as the inelastic equivalent of Rayleigh scattering and follows the same rule.

This theory predicts that Raman spectroscopy should be optimally performed in the near-UV not the NIR region. For example, excitation using the blue line of an  $\text{Ar}^+$  laser at 454 nm will produce essentially nine times more intense Raman scattering than 785 nm excitation. Yet in recent years, there has been an overwhelming trend toward using NIR excitation. This trend stems from a single interference source and frustration in Raman spectroscopy: fluorescence. Fluorescence occurs when the excitation is able to promote an electron into an excited electronic state. When impure samples or pure samples with low energy transitions are placed in a Raman spectrometer, the spectrum recorded using visible excitation often shows a broad fluorescence background, frequently devoid of any Raman features. A good rule-of-thumb is that the number of electronic states decreases with energy. Thus NIR excitation is often preferred since it will produce high quality Raman spectra devoid of any fluorescence interference unattainable with a higher energy visible excitation source.

A simple property of any spectrum can provide a more quantitative picture to the problem of fluorescence in Raman spectroscopy. The signal-to-noise ratio (S/N) describes the quality of the spectrum. A high S/N is desirable for viewing a spectrum for both qualitative analysis and for concentration determination with quantitative analysis. Obviously, the S/N can be increased two ways: an increase in signal or a decrease in noise. For example, if the Raman spectrum of cyclohexane is taken from a sample and has been filtered to remove any particulates, the S/N ratio

will improve linearly with increasing laser power (for relatively low laser powers) or as the square root of the integration time. If one takes a spectrum of cyclohexane with a fluorescent impurity, the S/N will not increase linearly with laser power. Longer integration times will be limited by the dynamic range of the detector. This originates from the dependency of the noise on the signal in spectroscopy. When visible photons are detected, they produce a noise equivalent to the variance of the signal. If a sample has a background fluorescence that increases with the laser power or integration time, noise will also increase. This leads to the fundamental question of whether Raman spectroscopy is a true zero-baseline technique.

The answer is that Raman spectroscopy rarely fits that description of zero-baseline. Most samples possess a background due to either inherent or impurity fluorescence. If NIR excitation circumvents or strongly reduces the background, the reduction in intensity due to the  $\nu^4$  dependence of the Raman signal becomes irrelevant compared to the noise produced by a large fluorescence background if visible excitation is used.

A second problem arises from the shape of the fluorescent background. If the background were linear, it could be easily subtracted to produce a high-quality spectrum, albeit noisy due to the noise produced by the high background. However, in addition to adding noise to the spectrum, the fluorescence creates broad features in the background that are often very difficult to remove. This leads to serious difficulties in quantitative analysis because the Raman signal above the baseline is proportional to the concentration, not the signal above a zero-baseline. It also can lead to small frequency shifts in qualitative Raman spectroscopy. NIR-Raman spectroscopy often leads to higher quality spectra due to the minimization of background signals from the sample.

### The Difference in Detection

The S/N is a function of the excitation in Raman spectroscopy and as already discussed above, Raman spectroscopy can strongly benefit from using NIR excitation. The detection method also affects the S/N and is still perhaps a point of controversy among Raman spectroscopists. The controversy stems from the quasiphoton nature of NIR light. One may prefer to consider the light particle in nature and count the photons or one may prefer to consider the light as a wave. To explain this duality and controversy, a freshman chemistry experiment can be used as an illustration.

Consider the simple process of weighing coins on a balance. Assume the weight of three coins needs to be determined using a balance. The common laboratory balance has a standard error of  $e$  while a very good analytical balance has an  $e$  of 0.0001 g. Thus, if weighing  $0.001 \pm 0.0001$  g or even  $10 \pm 0.0001$  g, the error is not dependent on the mass being weighed. The three coins individually will weigh  $m_1 \pm 0.0001$  g,  $m_2 \pm 0.0001$  g, and  $m_3 \pm 0.0001$  g. The accuracy can be improved by weighing the coins in pairs. In this case,  $m_1 + m_2 = m_{12} \pm 0.0001$  g,  $m_1 + m_3 = m_{13} \pm 0.0001$  g, and  $m_2 + m_3 = m_{23} \pm 0.0001$  g.

The three weights of each pair can be subtracted to find the individual weights. For example,  $m_1 = \frac{1}{2}(m_{12} + m_{13} - m_{23}) \pm e_T$ . The total error,  $e_T$ , can be found from the propagation errors in the three measurements. It is  $\{[\frac{1}{2}(e_1 + e_2 - e_3)]^2\}^{1/2}$ . If the errors are random, the equation can be simplified to  $m_1 = [\frac{1}{4}(e_1^2 + e_2^2 + e_3^2)]^{1/2}$  and as stated above, the balance has an error of  $e$  regardless of the mass. This leads to  $m_1 = [\frac{1}{4}(3e^2)]^{1/2}$  or  $3^{1/2}/2e$  or 87% of  $e$ . In the actual measurement, the weight of  $m_1$  would be  $m_1 \pm 0.000087$ . In general, the more coins that are weighed, the better the result. If  $N$  coins were weighed, the error would be reduced by  $N^{1/2}/(N - 1)$ , or for a 1000 coins, the error would be reduced to 3% of its original value. This may be perceived of as the basis of Fourier Transform Raman spectroscopy (FT-Raman spectroscopy). In FT-Raman, the Raman scattered light can be considered as waves that are allowed to interfere with each other to produce an interference pattern (interferogram) that can be mathematically converted by an inverse FT into a spectrum. The benefit, called Fellgett's or Multiplex Advantage, arises from putting the whole spectrum at once onto the detector. This is exactly analogous to placing the many coins on the balance at once to find the weight of an individual coin.

The controversy arises from the fact that optical detectors are not always like an analytical balance. As the energy of a photon decreases, the prominent detector noise becomes the thermal excitation of electrons in the detector. When this noise source dominates, the detector is similar to the analytical balance. When the energy of the photon is large, the thermal noise becomes insignificant. This transition occurs in the NIR region. The noise from high-energy photons arises from their quantum nature. If individual photons were counted for 1-s intervals, in one interval, 100 may be counted, in the next 95, in the next 105, and so on. These differences occur because the photons are random events and may happen more often during one period than the next. Statistics dictate that the error or standard deviation of photons counted is the square root of the number

of photons being counted or as stated earlier, the signal is equal to the variance in the signal.

Using the weight of the coins, the error of the balance can be calculated. The same calculations can be made as described above, except the error over two weighings is  $2^{1/2}e$ . Calculations show that for  $m_1$ , the error is  $\pm(3/2)^{1/2}e$  or  $1.22e$ . The error has increased instead of decreasing. What was once an advantage for one detector is now a disadvantage for another. The result is two camps of Raman spectroscopists. When a sample is very fluorescent, even in the far-red, it is best to move further into the IR and use FT-Raman spectroscopy. If fluorescence can be eliminated or reduced, conventional NIR-excited dispersive Raman spectroscopy provides the best option.

## Instrumentation

For many years, NIR excitation of Raman spectra was not considered viable; however, things changed with several key instrumentation developments. CCDs now allow parallel detection of Raman spectra with high quantum efficiency and low noise. Volume-holographic filters and gratings improve overall throughput and provide elastic light rejection for Raman spectrographs. In addition, economical, long-life laser diodes provide sufficient power for Raman applications and optical fiber probes allow remote chemical analysis by Raman scattering.

### Laser Source

The sources used in modern Raman spectroscopy are almost always lasers because their high intensity is necessary to produce Raman scattering of sufficient intensity to be measured with reasonable signal-to-noise ratio. Argon ion lasers operate at 488 or 514.5 nm, krypton lasers operate at 530.0 or 647.1 nm, and helium/neon (He/Ne) lasers operate at 632.8 nm. In NIR-Raman spectroscopy, the laser sources used are the diode laser (782 or 830 nm) and Nd/YAG (1064 nm). NIR sources have two major advantages over shorter wavelength lasers. The first is that they can be operated at much higher power (typically up to 50 W) without causing photodecomposition of the sample. The second is that they are not energetic enough to populate a significant number of fluorescence producing excited electronic energy states in most molecules. Consequently, fluorescence is generally much less intense or nonexistent with these lasers. The Nd/YAG line at 1064 nm is particularly effective in eliminating fluorescence. The two lines of the diode array laser at 782 and 830 nm also markedly reduce fluorescence in most cases.

Figure 2 provides an example where the diode laser source completely eliminates background

**Figure 2** Effect of different laser wavelengths, 633 nm (He/Ne laser) and 785 nm (diode laser), on the reduction of fluorescence in the analysis of iodoanisole.

fluorescence. The sample was iodoanisole and most of recorded signal using visible excitation arises from the fluorescence of that compound. The lower curve was obtained with conventional Raman equipment using the 633-nm line from a He/Ne laser for excitation. The upper curve is for the same sample recorded with a spectrometer equipped with a diode laser that emitted at 785 nm. Note the absence of fluorescence background signal.

Two basic cavity configurations are used to construct and stabilize NIR-Raman laser sources. The first design, the Littrow configuration, collimates light from the laser diode and sends it to the grating at a specific angle of incidence. The first-order diffracted light is sent directly back to the laser to provide optical feedback across a narrow wavelength range. The output beam is the light that is reflected from the grating, thus the output is at an angle that is approximately twice the angle of incidence from the optical axis. Because of its simple design, the external-cavity length can be quite short, resulting in wide spacing of the external-cavity mode. This spacing facilitates single-frequency operation where the goal is to have only one external-cavity mode fall within the bandwidth of the diffraction grating. The bandwidth of the grating is relatively large because the Littrow configuration uses a single-pass geometry.

In the second design, the Littman configuration, the collimated laser light strikes the grating near the grazing incidence so that the diffracted order does not return to the laser directly. Instead, the diffracted

light is reflected by a mirror, diffracted by the grating a second time and then returned as optical feedback to the laser diode. The advantage of the double-pass geometry is that the grating bandwidth is less than half of what it is in the Littrow case but the external cavity length tends to be longer. In practice, the Littman configuration is usually selected when narrower-frequency operation is desired.

### Spectrometer

A Raman spectrophotometer analyzes the radiation scattered by molecules when they are illuminated with monochromatic exciting radiation. Currently, most Raman spectrometers are either FT instruments equipped with cooled germanium transducers or multichannel instruments based upon CCDs. These transducers, in contrast to photomultiplier tubes, are sensitive to radiation at 785 nm produced by diode lasers, which provide Raman excitation of many compounds without significant fluorescence. CCDs are not sensitive to the 1064-nm radiation from an Nd/YAG laser.

Figure 3 is a schematic representation of a typical NIR-Raman dispersing spectrometer with a CCD in the Littman configuration. The source is a diode laser and filter system that yields radiation at 785 nm. This beam is focused on the end of the excitation filter by means of a lens, and the Raman emission is transmitted through the collimating lens. A diffraction grating disperses the radiation and reflects it onto a CCD that is made up of a large number of pixels. These pixels store the charge produced by the light quanta. Since the spectral information seen by the individual pixels is accumulated simultaneously, an

array with  $n$  pixels is equivalent to  $n$  spectrometers accumulating separately or one spectrometer working  $n$  times.

### Applications

NIR-Raman spectroscopy has been used for a number of applications and is particularly useful for biological and biomedical uses. Fluorescence has been a limiting factor for much Raman analysis of biological samples, particularly whole-cell or whole-tissue samples. NIR excitation reduces interference from fluorescence and decreases photoinduced degradation of the sample, enabling researchers to obtain spectra for a variety of biomaterials and living cells.

Interest in both *in vivo* and *in vitro* use of NIR-Raman spectroscopy of tissues for diagnostics continues to grow. NIR-Raman has been evaluated as a diagnostic tool for cervical precancers. Although spectra could not be collected *in vivo* due to long integration times, NIR-Raman was found to have specificity that was superior to standard methodologies, such as colonoscopy and cytology, for differentiating squamous intraepithelial lesions (SIL) from non-SIL. Several research groups have described NIR-Raman instrumentation with CCD detection for biological tissue analysis, both *in vivo* and *in vitro*. In a specific study, an 810-nm excitation wavelength was used for *in vitro* laboratory analysis of aorta tissues. Subsequent work showed that fluorescence interference in tissue Raman spectra could be reduced even further using 830-nm excitation without compromising CCD sensitivity. The usefulness of NIR-Raman coupled with CCD detection for

**Figure 3** Typical Raman dispersing spectrometer with a CCD in the Littman configuration. (Courtesy of DeltaNu, Laramie, WY.)

studying cancerous changes in the colon, urinary bladder, breast, and soft tissue sarcomas has also been examined.

NIR-Raman has found applications in the pharmaceutical industry. McCreery and colleagues reported the use of the technique for identification of pharmaceuticals inside amber vials. Even with the signal attenuation through the glass, adequate spectra were obtained for determination of vial content with 1–60 s integration times. Using a library of spectra, identification of the pharmaceuticals in the vials was performed and identification was found to display accuracy between 88% and 96%. This work demonstrated the potential of NIR-Raman for online process monitoring.

The environmental community has also found uses for NIR-Raman analysis. A continuous method was developed by Weissenbacher and colleagues to detect trace organic pollutants using flow injection analysis and surface enhanced Raman spectroscopy (SERS). This method uses NIR excitation and FT-SERS detection to detect parts per million of pesticides in aqueous solutions. In this study, the authors describe the simultaneous detection of two pesticides, carbendazim and metazachlorine.

A variety of industrial processes benefit from the use of NIR-Raman spectroscopy. In a study examining unleaded petroleum gasoline, with excitation at 514 nm from an argon laser, no Raman features were observed above the strong fluorescence. With He/Ne laser excitation at 633 nm, several Raman features appeared above the background. With excitation at 785 or 852 nm, a good quality Raman spectrum was obtained. In the textile industry, NIR-Raman was used to examine ready-made textiles for the discrimination of the different raw materials.

NIR-Raman has been introduced for use into the food processing industry. In the production of oils and fats, the determination of the amount of unsaturation, such as *cis* and *trans* isomers, can be important for food processing and food labeling. NIR-Raman was reported to measure the total unsaturation and the *cis* and *trans* isomers online during the production process. Fluorescence interference with visible excitation of many fats was

drastically reduced at NIR wavelengths. In addition to food processing, NIR-Raman has been used for determination of food quality as the main components of food (carbohydrates, proteins, and lipids) all show characteristic Raman lines using NIR detection.

The pairing of SERS with NIR detection has proved to be a powerful DNA detection technique. NIR-SERS was reported to provide excellent discrimination against fluorescent interference and was nonresonant with most molecules. This allowed greater excitation intensities without photobleaching or destruction of the analyte. In one study, Kneipp and colleagues used this technique in rapid DNA sequencing to detect single-molecule DNA bases or nucleotides. NIR-SERS provided a method for detection and identification of the single DNA base, adenine, without any additional labeling. This study reported trace detection levels of adenine and AMP with well-resolved spectra.

## Introduction

Surface enhanced Raman scattering (SERS) is a sensitive spectroscopic technique for the detection and

characterization of analytes adsorbed on suitable metal surfaces. The effect was first discovered experimentally in 1974 by Fleischmann *et al.*, who reported very intense Raman bands from pyridine adsorbed onto an anodized silver surface. They attributed this strong signal to the presence of a large number of pyridine molecules present at the roughened electrode surface due to its large surface area. However, in 1977 Jeanmaire and Van Duyne, and Albrecht and Creighton, independently recognized that the increase in intensity could not be accounted for simply by the number of scatterers present. They observed that compared with the equivalent concentration of pyridine in solution, an enhancement of  $\sim 10^6$  in Raman scattering was obtained. They concluded that an intrinsic surface enhancement effect played a fundamental role in producing the enhanced Raman scattering.

In the basic process of SERS, the analyte is adsorbed onto a roughened metal surface of a suitable metal, usually silver or gold. On excitation of this surface with a laser beam, a change in polarizability of the analyte occurs in a direction perpendicular to the surface, leading to the enhanced scattering. The rough surface required for scattering can be provided in a large number of ways. Common methods are to use aggregated colloidal particles, roughened electrodes, or thin cold-deposited metal films.

## Mechanisms of Surface Enhancement

Since the discovery of SERS there has been much debate regarding the origins of the effect. However, it is generally accepted that there are two main contributions to the enhancement process, namely electromagnetic enhancement and charge transfer or chemical enhancement.

### Electromagnetic Enhancement

The collective excitation of an electron cloud on the surface of a metal is termed a surface plasmon. Surface roughness or curvature is required for the scattering of light by surface plasmons. The electromagnetic field at the surface is greatly enhanced upon surface plasmon excitation. If an analyte is present on the roughened metal surface, the molecule experiences a large electric field at the surface. The intensity of the Raman scattering is dependent upon the induced polarization caused by the electric field, and consequently Raman scattering is amplified by a factor of  $10^4$  or greater. Electromagnetic enhancement does not require a direct metal-analyte bond but becomes weaker the larger the separation between the analyte and the surface. It can occur

with a separation of up to  $\sim 20 \text{ \AA}$ . Surface selection rules have been developed based on the electromagnetic approach.

### Charge Transfer

Charge transfer assumes a bond is formed between the analyte and the metal surface. The energy levels of the molecule are shifted and broadened so that they overlap with the Fermi level of the metal and new electronic states are created. On absorption of the incident light by the metal these states serve as resonant intermediate states, allowing efficient charge transfer between the metal and the analyte and hence enhanced Raman scattering. The enhancement obtained in this manner is confined to being a first layer effect. In general, the enhancement predicted is  $\sim 10^2$ .

## Advantages and Disadvantages of SERS

SERS offers several advantages over normal Raman or resonance Raman scattering. The huge increase in signal intensity allows an extended concentration range to be studied, with detection limits considerably lower than those offered by resonance Raman scattering. Fluorescence from the analyte is quenched due to its proximity to the metal surface, providing an alternative, nonradiative route for energy loss. There is however a much broader low-intensity fluorescence from the SERS process. In addition, for studies of processes such as surface-ligand adhesion and corrosion, it allows the study of an adsorbate at less than monolayer coverage on a suitable metal surface *in situ*, in contact with water and other solvents.

SERS does, however, have some limitations. For the SERS effect to occur, the analyte needs to be adsorbed onto or in close proximity to the roughened metal surface, and only a few metals have so far been shown to be efficient at providing surface enhancement. SERS intensities are also dependent on the roughness of the metal surface, and there are significant problems associated with the preparation of reproducible substrates with uniform roughness features. The spectra obtained are also dependent on the orientation of the molecule on the metal surface, and vibrations with little to no intensity in normal Raman scattering can become relatively intense. This can in some cases make it difficult to identify the analyte positively. Further, contamination can also be a problem. Since SERS is very sensitive, it is possible that very small amounts of a contaminant can be enhanced, and if the analyte to be considered does

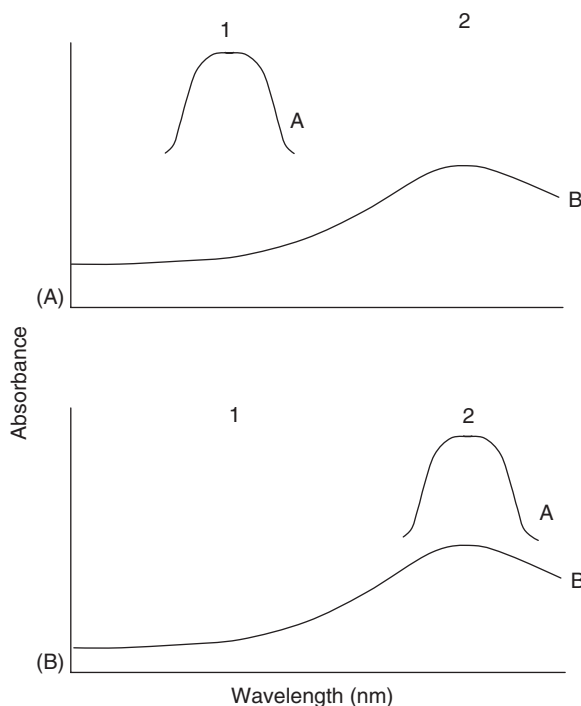

not adsorb efficiently or does not give good SERS, the contaminant can easily dominate the SERS. These problems limit the use of SERS as a quantitative analytical method. However, these problems are largely overcome if surface-enhanced resonance-Raman scattering (SERRS) is used.

## Surface Enhanced Resonance Raman Scattering

So far in this article, both colored molecules and colorless molecules have been treated simply as analytes, and the enhancement has been taken as a combination of electromagnetic and chemical enhancement. However, there are crucial differences where a colored adsorbate is adsorbed onto a metallic surface such that the plasmon resonance frequency and the frequency of an absorption band are close to the frequency of the incident light. This combination of surface enhancement and molecular resonance is called SERRS. Stacy and Van Duyne first reported SERRS in 1983. The increase in sensitivity over SERS can be quite large, with total enhancements of up to  $10^{14}$  reported.

When used practically, there are various combinations of laser frequency, plasmon resonance frequency, and molar absorptivity of the analyte that can be employed to obtain a condition that can be deemed to be SERRS rather than SERS. These are shown diagrammatically in Figure 1. If the excitation is matched to the molecular absorption maximum (Figure 1A), the surface selection rules expected for SERS are much less effective. This is due to the polarization of the laser excitation altering on interaction with the chromophore during the scattering process. This results in a degradation of the effective input polarization required for SERS selection rules, making SERRS less sensitive to the orientation of the molecule to the surface. This usually means that the spectrum resembles that of the resonance spectrum in solution, so that positive identification of the analyte is possible. In addition, the extra enhancement of the analyte discriminates against the detection of contamination. Thus, SERRS is more readily applicable for the development of methods for quantitative analysis.

A second possible arrangement illustrated in Figure 1A is where the laser excitation is set away from the absorption maximum of the adsorbate and at the maximum of the plasmon resonance. This is described as preresonant scattering, and often SERRS taken in this way is written as SE(R)RS. The advantages of resonance still apply over quite a wide range of frequencies, gradually tailing off to SERS. Thus, SE(R)RS makes it simpler to pick out individual

**Figure 1** The different arrangements for SERRS: the curves represent (A) molecular absorbance and (B) plasmon resonance. In (A) the molecular absorbance maximum and the plasmon absorbance maximum do not coincide: position 1 represents excitation at the absorbance maximum, 2 that at the plasmon maximum. In (B) the molecular absorbance and the plasmon maximum coincide: position 1 represents excitation away from the absorbance and plasmon maximum where the spectrum has a preresonant component, 2 that at the absorbance maximum and plasmon maximum. (Rodger C, Smith WE, Dent G, and Edmondson M (1996) Surface-enhanced resonance-Raman scattering: An informative probe of surfaces. *Journal of Chemical Society, Dalton Transaction* 791–799; reproduced by permission of The Royal Society of Chemistry.)

resonant molecules in the presence of a matrix of interferences, but the further away the excitation is from molecular resonance, the more the effect will be dependent on the angle of the adsorbate to the surface. For surface studies this is a key point, and consequently this arrangement may be preferred for some surface analyses.

Figure 1B illustrates an alternative case in which the molecular chromophore coincides with the surface plasmon maximum. Similar considerations will apply to those discussed for the case represented in Figure 1A, but a further increase in sensitivity is likely with excitation at the molecular and plasmon resonance frequency. The orientation dependence will become more apparent the greater the difference in frequency between the excitation frequency used and the absorbance and plasmon maximum as the conditions become more appropriate for SERS (1 in

**Figure 2** Resonance Raman and SERRS spectra of rhodamine 6G with excitation at 514.5 nm. The high fluorescence background is effectively quenched in the SERRS spectrum due to adsorption of the rhodamine onto the surface of the silver nanoparticles. (Reproduced with permission from Rodger C and Smith WE (2002) SERS. In: *Handbook of Vibrational Spectroscopy*. New York: Wiley; © John Wiley & Sons Ltd.)

Figure 1B). As a consequence the sensitivity will decrease.

Where SERRS can be applied, it offers many advantages over Raman scattering, resonance Raman scattering, and SERS. It provides both vibrational and electronic information on the adsorbate. Very wide concentration ranges can be studied, and single molecule detection is easier. A further major advantage is the quenching of fluorescence by the surface, which allows fluorescing dyes, which are ineffective in visible resonance Raman studies, to give very good SERRS. For example, rhodamine 6G fluoresces strongly in the visible region, preventing the use of normal Raman scattering, but gives good SERRS (Figure 2). In addition, there is less dependence of the signal on orientation. The combination of sensitivity, selectivity, and robustness of signal makes SERRS a very sensitive and selective form of vibrational spectroscopy that can be used semiquantitatively or qualitatively.

## SERS Substrates

SERS activity requires that very specific substrates be prepared. The metal chosen requires a plasmon in the frequency region close to that of the excitation laser. In addition, the ratio of scattering to adsorption of the substrate is important. Since visible frequency lasers are widely used in this technique, silver, gold, and copper, which have plasmons resonant with visible light, are obvious effective substrates. Silver is particularly useful, having a better ratio of scattering to adsorption in the visible region than gold. Copper tends to be too chemically reactive, and although other metals including lithium, sodium, and some

transition metals are effective, silver is by far the most widely used. It is possible to form reasonably time-stable roughened silver surfaces that can be used under normal laboratory conditions.

Many types of SERS-active substrate have been made, each containing many microscopic metal domains. These include the following: electrode surfaces roughened by oxidation–reduction cycles; island films consisting of small metal particles; cold-deposited films prepared by evaporation or sputtering in a vacuum; lithographically produced assemblies; metal gratings; metal colloids prepared by reducing a dissolved metal salt with an appropriate reducing agent; metal colloids encapsulated in sol–gel-derived xerogel layers; silver particle-doped cellulose gel films; and microbeads as a carrier of silver colloid. Metal nanoparticles, usually prepared as colloidal suspensions, are one of the most widely studied SERS substrates. They exhibit unique optical properties due to excitation of the surface plasmons. The frequency of the surface plasmon resonance depends strongly on the size, shape, and dielectric environment of the particles. Additionally, when particles are closely spaced, the surface plasmons of individual particles interact to create new resonances dependent upon the interparticle distance and the incident angle and polarization of the light. Thus, optical properties of individual particles and arrays of interacting particles can be conveniently tuned.

Significant progress has been made in controlling the size and shape of metal nanoparticles. Monodisperse single crystal nanocubes, nanorods, and nanoshells have all been prepared using simple methods. The size and shape of gold particles are more easily controlled than those of silver, and consequently silver-clad gold nanoparticles have been prepared and shown to possess distinct optical properties.

Silver colloid is popular due to the relative ease of manufacture, low cost, and stability. One widely used method of silver colloid preparation is citrate reduction of silver nitrate (Figure 3). This results in an overall net negative charge on the colloid, which is high compared with many preparations (Figure 4). As a result, the colloid is stable for months and even years, and in some cases, with careful attention to detail, quantitative SERRS can be obtained from this colloid with relative standard deviations of less than 5%. There is, however, a change in enhancement with time, and so a standard needs to be used.

## Studies of SERS/SERRS Enhancement

The reason for SERS/SERRS enhancement has been studied by a number of groups. It has been shown that aggregated silver colloids produce fractal

**Figure 3** A representative transmission electron microscopic image of citrate-reduced silver colloid. The particles are mainly hexagonal, with a largest face diameter of  $\sim 36$  nm. A few rods are present. (Reprinted with permission from Faulds K, Littleford RE, Graham D, Dent G, and Smith WE (2004) Comparison of surface-enhanced resonance Raman scattering from unaggregated and aggregated nanoparticles. *Analytical Chemistry* 76: 592–598; © American Chemical Society.)

**Figure 4** Representation of the surface of a Lee and Meisel colloidal particle. The citrate is believed to be bonded to the silver, which is present as  $\text{Ag}^+$ , with negatively charged carboxylate groups. (Rodger C, Smith WE, Dent G, and Edmondson M (1996) Surface-enhanced resonance-Raman scattering: An informative probe of surfaces. *Journal of Chemical Society, Dalton Transaction* 791–799; reproduced by permission of The Royal Society of Chemistry.)

clusters. Upon excitation, the electromagnetic field over a fractal object is not distributed uniformly but is localized in hot spots much smaller than the wavelength of light (10–30 nm). A large volume of the fractal therefore remains inactive or active at a lower level, while the portions of the fractal within these hot spots carry the full activity. This

localization of optical excitation indicates that very high electromagnetic fields lead to the huge enhancement of Raman scattering. Other experiments have shown an anomalously high enhancement in the first layer, suggesting the need to consider the charge transfer or chemical mechanism of enhancement as well as the electrochemical enhancement.

Since only analytes attached to or close to metal surface are enhanced, the need for effective surface attachment is crucial if reproducible results are to be obtained. In many early experiments this was widely ignored. Commercial dyes were simply added to colloid or placed on surfaces and the results, where favourable, have been reported in many studies. The problem with this approach is that the surface chemistry of an element such as silver is complex. Little is understood about the surfaces on which the analyte is adsorbed, particularly in aqueous solution or, as is often done, with particles prepared in aqueous solutions and dried out on a surface for investigation. Further, where colloidal suspensions are used, it is common practice to aggregate the colloid in order to shift the frequency of the plasmon to a value that would place it in resonance with the laser. In fact, it is clear from ultraviolet–visible absorption that a range of clusters are made in most conditions and only a few are likely to be in resonance with the laser. However, this gives a bigger SERS enhancement than for single particles.

The aggregating agent usually breaks up a stable colloid by reducing the charge on the surface. This can often happen by chemical action. Under the aerobic conditions used in most experiments, and shown in some to be essential for good SERS, the silver surface in the colloidal suspension is likely to be coated with a silver oxide or related layer containing silver(I) ions. It may also contain other adsorbed molecules from the preparation of the colloid. When a reagent such as sodium chloride is added to this surface, it is likely that a layer of silver chloride will form. This is known to be the case for electrode surfaces. With solid substrates, similar approaches are sometimes taken. For example, using the most commonly used analyte for fundamental studies, rhodamine 6G, the normal process for obtaining the best signals is to activate the surface with the sodium chloride. This particular combination of rhodamine and sodium chloride does give a more effective spectrum than without the addition of sodium chloride. However, studies of other analytes with colloidal suspensions have shown that sodium chloride is not always the most effective aggregating agent and no special activation procedures have been required. Additionally, with higher concentrations of rhodamine, not all the dye adsorbs and large fluorescent

**Figure 5** Chemical structure of two dyes specifically designed to complex strongly to the silver surface for effective SERS. (A) 4(5'-azobenzotriazolyl) 3,5-dimethoxyphenylamine; (B) 5-(2-methyl-3,5-dinitro-phenylazo) quinolin-8-ol.

backgrounds are obtained (see Figure 2). This can limit the use of SERRS and is often a problem where weak signals are obtained, and the temptation is to use higher, not lower, concentrations.

Thus, for quantitative work and for obtaining a better understanding of the effect, effective surface adhesion is essential. In addition, the simpler the nature of the surface, the easier it is to understand the nature of the enhancement. For this reason, a set of special dyes has been developed for SERS/SERRS. These contain groups added to the dye specifically to obtain metal complexing with silver ions present on the surface. Two effective groups of this type are shown in Figure 5. One contains the benzotriazole group, known to be an effective method of preventing tarnishing in silver due to its strong attachment to the surface. The other contains an 8-hydroxy-quinoline group, which will create a complex with silver ions on the metal surface that is insoluble. Both these reagents have proved to be effective for obtaining SERS/SERRS with sodium chloride and other aggregating agents, including organic aggregating agents such as poly-L-lysine.

## Single Molecule Spectroscopy

In 1997 two groups independently claimed single molecule detection using SERS/SERRS using different approaches. In some of the single molecule studies, the difference between SERS and SERRS is ignored, but most, not all, of the studies use chromophores. Nie and Emory reported detection of single rhodamine 6G dye molecules adsorbed on immobilized single silver nanoparticles using SERRS, and Kneipp *et al.* reported detection of a single molecule of crystal violet adsorbed on aggregated clusters of silver particles in a colloidal suspension using near infrared excitation. The large SERS

enhancement was attributed to excitation of the coupled surface plasmons of the colloidal aggregate. The SERS enhancement quoted by both groups for the detection of single molecules is of the order of  $10^{14}$ . Such enhancements are many orders of magnitude greater than predicted ensemble averaged values. This can be attributed to the removal of population averaging effects, whereby all the molecules and particles are assumed to contribute equally to the observed signals. Instead, only the active particle or active site is considered. Other groups have subsequently reported single molecule detection using SERS.

Although detection of a single molecule adsorbed onto an immobilized single silver nanoparticle has been reported, studies on the protein hemoglobin adsorbed on immobilized colloidal particles revealed that the minimum state of aggregation necessary for SERS detection of a single hemoglobin molecule was the dimer. Detection of molecules adsorbed to single particles was not observed. Consequently, it is suggested that the surface enhancement is predominantly electromagnetic in nature and dominated by the increased local electric field between the two particles. Calculations suggest the maximum electromagnetic contribution to SERS enhancement for two interacting spheres to be of the order of  $10^{11}$ , and therefore an additional enhancement of  $10^3$  is required to explain the enhancement factors necessary for single molecule detection. This extra enhancement may be electromagnetic due to further surface roughness present on individual particles or may be chemical in nature. It is proposed that the additional electromagnetic enhancement is obtained only under special positions such as the interstitial site between two particles and outside sharp surface protrusions.

## Applications of SERS

### Sensors

Due to the molecular specificity of SERS/SERRS, combined with its inherent sensitivity, it has found utility in a wide range of applications, only a few of which can be described here. The development of SERS sensor technology has allowed the detection and identification of seven structurally similar monosaccharides in aqueous solution using a sample volume of only  $5\mu\text{l}$  with a concentration of  $1 \times 10^{-2} \text{ mol dm}^{-3}$ . This has led to the initial development of a glucose-based biosensor with true *in vivo*, real time, minimally invasive sensing.

The development of a volatile organic compound sensor using SERS detection has also been reported. The SERS substrate is chemically modified with a

thiol coating to prevent oxidation of the roughened silver surface and attracts the analyte of interest to the SERS surface. Detection of chlorinated solvents, aromatic compounds, and methyl *t*-butyl ether have all been demonstrated.

### Drugs

There is considerable interest in the development of novel platinum-based anticancer drugs that overcome the disadvantages associated with the widely used drug cisplatin, namely its inactivity against some types of tumors and toxic side effects. SERS has been shown to be suitable for the characterization of platinum complexes at physiological concentrations, allowing the determination of binding strengths of different ligands.

The large SERRS intensities from the anticancer drug mitoxantrone have been used to provide a quantitative method of detection. The method uses a flow cell, which causes a dilution of plasma and serum samples, thus overcoming the fluorescent background. Even with these dilution steps the detection limits are superior to the previously published high-performance liquid chromatography (HPLC) method and are sufficiently good to be used for clinical analysis. Since the SERRS technique takes minutes from sample introduction to detection, and the chromatography technique hours, the SERRS technique could be considered the technique of choice for analysis of this drug.

### Intracellular SERS

SERS from living cells has been reported using several techniques. Etched and silver-coated glass fiber tips have been used as the SERS substrate, allowing the recording of spectra of biological samples, such as plant tissue and microbiological cells, with high spatial resolution. The deposition of colloidal gold particles inside single living cells by fluid-phase uptake has been demonstrated, providing strong SERS signals from the native chemical constituents of the cells. The sensitivity of SERS allowed measurements to be made in relatively short collection times (1 s for one mapping point) using 3–5 mW of near infrared excitation. SERS mapping over a cell monolayer with a 1  $\mu$ m lateral resolution showed different Raman spectra at almost all places, reflecting the very inhomogeneous chemical constitution of the cells. This has opened up exciting possibilities for the study of cell biology and biomedical studies.

### Atomic Force Microscopy/Raman

Atomic force microscopy (AFM) uses a fine tip to probe surfaces. It has extremely high resolution. By

adding a roughened silver coating to AFM tips, a technique has been developed whereby when the AFM tip is touched on the surface it is irradiated with a laser, providing good SERS. The advantage of this technique is that the effective resolution of the technique is the dimension of the tip and consequently is much smaller than optical dimensions. The tip position is known from the AFM scan. This type of method has been used for analysis of thin films, which are undetectable with Raman microprobe systems but easily acquired with a suitably gold-coated AFM tip. More recently, a combined scanning electron microscope/Raman scattering detection system has been created. It is possible to detect the Raman scattering during the time of the SEM scan. This provides detailed structural information on the surface in a noncontact manner, which is faster and sometimes more effective than AFM. Since Raman scattering only occurs from the tip, and the tip position is known from the SEM, the dimensions of the tip are essentially the resolution of the instrument.

### DNA

The single molecule detection capacity of SERRS has been used to develop analytical techniques for DNA. These can use either a substrate or a colloid. In either case, this is most effective when the label is within the monolayer of the surface and hence the largest SERRS enhancement can be obtained. Methods have been developed that enable spatial separation of different events and their detection on a substrate. The use of SERS to monitor DNA hybridization of a fragment of the breast cancer susceptibility gene, BRCA1, on modified silver surfaces has been shown to be effective.

A number of SERRS active DNA probes with different dyes have been synthesized that are used with colloids. Detection limits that are better than those obtained with fluorescence can now be obtained with SERRS. In addition, whereas fluorescence gives a very broad signal, SERRS gives a sharp signal and consequently is much more effective for multiplexing. This technique has been improved by the addition of a flow cell and in particular a lab on a chip flow cell, where control of the process of aggregation through the laminar flow region of the chip has shown a great improvement in quantitation as well as an improvement in sensitivity. The sensitivity of this method is known to be down to single molecule level, and it is possible to obtain this using commercial equipment within a maximum of 10 s. This technique is showing considerable promise for more effective multiplexed forms of DNA analysis (Figure 6). Recently, multiplexing of six probes with

**Figure 6** SERRS from 2,5,1',3',9'-hexachloro-6-carboxyfluorescein (HEX) and rhodamine 6G labeled oligonucleotides at  $2 \times 10^{-9} \text{ mol l}^{-1}$  (1 s accumulation time). The unique SERRS spectral fingerprints from each dye allow multiplex analysis of SERRS/DNA complexes. (Reproduced with permission from Graham D, Mallinder BJ, and Smith WE (2000) Detection and identification of labeled DNA by surface enhanced resonance Raman scattering. *Biopolymers (Biospectroscopy)* 57: 85–91; © John Wiley & Sons, Inc.)

gold nanoparticles has been demonstrated, indicating the large multiple detection capability for SERRS/DNA assays.

### Distance Detection

The ability to obtain sharp molecularly specific spectra from SERRS prompted the concept that a number of codes could be written simply by changing the combination of analytes and by changing their concentration. In this way, it is believed, hundreds of thousands of codes can be written that can be read using a Raman spectrometer without any spatial separation. The initial demonstration for this for one dye has shown that Raman scattering from suitable polymer films can be detected at up to 10 m (Figure 7) and therefore there is considerable potential for further expansion in this direction.

### Proteins

One of the first important demonstrations of SERRS was to detect heme groups in proteins. It is a good

**Figure 7** Change in spectral intensity as the distance from the sample is increased. (Reproduced with permission from McCabe A, Smith WE, Thomson G, *et al.* (2002) Remote detection using surface enhanced resonance Raman scattering. *Appl Spectrosc* 56: 820–826.)

example of the selectivity of the method in that practically no signals are obtained from the protein other than from the heme group. The heme on the other hand can be detected down to below monolayer coverage, although a monolayer is often used since it helps prevent protein degradation. A silver colloid stabilized with citrate layers also helps. The advantage of SERRS is that marker bands are available for the oxidation state, spin state, and coplanarity of the vinyl groups with the heme group. In addition, compared with resonance Raman scattering, it is easier to obtain SERRS from weaker chromophore absorption bands such as the Q band.

### Bacteria

The treatment of bacteria with sodium borohydride provides a nucleating substrate for the reduction of silver ions, forming a rough silver metal coating around the microorganism. Intense SERS of the coated bacteria showed four different types of bacteria to all produce similar spectra, suggesting that the spectra are selective and sensitive to a specific molecular species that dominates the spectra and that is found in all the bacteria analyzed.

### Introduction

Remote gas sensing is the process of measuring, or detecting, a gas at some point that is distant from the location where the analysis is carried out.

Various methods have been developed for remote gas sensing. These include: differential optical-absorption spectroscopy (DOAS), differential absorption lidar (DIAL), and a number of methods that use spectroscopic methods with an atmospheric path in place of a laboratory long-path cell, for example: tunable diode laser absorption spectroscopy (TDLAS) and Fourier transform infrared (FTIR) spectroscopy.

Generally, remote gas-sensing methods are sensitive to the presence of the target species at extended ranges, either intrinsically or as a result of their operation over different paths. Consequently, remote gas-sensing methods have applications to the measurement of poorly mixed atmospheres or when an averaged value for the concentration along a path is required. They also have advantages over point-sensing methods when measuring gases in locations that are inaccessible (e.g., at altitudes significantly above ground level) or whose location within a specified area is not known exactly.

Remote gas-sensing methods have often been considered to be competitors to point gas-sensing methods, which are only able to measure gases at the location of the apparatus. The examples given here

show that the two approaches are complementary and that remote gas-sensing methods are most likely to be applied effectively in applications that cannot be addressed by point sensing methods.

There are various methods that meet the definition of remote gas sensing in part but are not discussed here. These include sensors linked by optical fibers, or operated along the length of an optical fiber. None of these methods depend on atmospheric propagation, which is the common feature of the methods discussed here.

### Measurement Principle

In this overview, the basic principle of all optical remote gas-sensing methods is introduced and is used to explain how the accuracy and sensitivity with which a target gas can be measured are defined by the spectroscopic properties of the gas itself. These properties define the region of the spectrum in which it has significant absorption features together with their strength and structure.

The relationship between the intensity of a beam of electromagnetic radiation before and after it has traversed a path from range  $r' = 0$  to  $r' = r$  is given by the Beer–Lambert law:

$$I(r) = I(0) \exp \left( - \int_0^r [A(r') + \alpha C(r')] dr' \right)$$

where  $I(0)$  is the intensity of the light launched along the path and  $I(r)$  is its intensity at range  $r$ . The exponent includes all of the terms relating to the extinction and scattering of the beam. Since the atmosphere itself determines them, they are functions of the range. They can be conveniently divided into two groups. First, the absorption by the target species is given by the product  $\alpha C(r)$ , where  $\alpha$  is the

absorption coefficient and  $C(r)$  is the concentration at range  $r$ . Second,  $A(r)$  is the total optical attenuation along the path arising from all other mechanisms. These might include:

- Mie or Rayleigh scattering by aerosols,
- absorption by aerosols or other species, and
- absorption losses in the transmission or receiving optics of the remote gas-sensing system itself.

Both  $\alpha$  and  $A(r)$  are functions of the wavelength of the radiation as well as the range. A major challenge in practical applications of some remote gas-sensing methods is to distinguish changes in  $\alpha C$  from those in  $A$ . This is equivalent to establishing a 'zero level' for the measurement and is discussed under the section Calibration.

It can be seen from this simple analysis that the fundamental performance of a remote gas-sensing method in detecting a specific target gas is determined by  $\alpha$ . The spectral regions in which it might be possible to detect the target species are determined by the strength and structure of  $\alpha$  at wavelengths at which there is small or negligible absorption by other species present in the atmosphere.

The performance of any specific remote gas-sensing system is determined by its capability to detect changes in  $I(r)$  with respect to  $I(0)$ . This is usually expressed in terms of the signal-to-noise ratio.

## Absorption of Target Gases and of the Atmosphere

The monitoring of target gases in the atmosphere has to be undertaken in the presence of absorption by the gases normally present in the atmosphere. This imposes some important practical limitations on remote gas sensing.

In the ultraviolet spectral region, the short-wavelength monitoring limit in the atmosphere is set by the absorption of atmospheric oxygen. It absorbs weakly in the 260–230 nm range, and then increasingly strongly until at a wavelength of  $\sim 210$  nm the atmosphere is almost completely opaque. A 'clean' atmosphere is essentially transparent from this limit through the ultraviolet and visible spectral regions. A number of common atmospheric pollutants absorb in this region, including nitrogen monoxide, sulfur dioxide, nitrogen dioxide, ozone, and the single aromatic ring hydrocarbons. Hence, all of these species are readily detected by remote gas sensing in the ultraviolet spectral region.

In the infrared spectral region, some wavelength regions are inaccessible to remote gas sensing because of absorption by atmospheric carbon dioxide

**Table 1** Gases with characteristic absorption spectra that are potentially detectable by remote gas-sensing methods

220–900 nm spectral region	2–5 $\mu\text{m}$ spectral region	8–13 $\mu\text{m}$ spectral region
SO <sub>2</sub>	CO <sub>2</sub>	NH <sub>3</sub>

	COS	
	H <sub>2</sub> S	
	NH <sub>3</sub>	

(particularly the ranges 3–4  $\mu\text{m}$  and greater than 14  $\mu\text{m}$ ) and water (particularly in the ranges 2.5–3  $\mu\text{m}$  and 5–8  $\mu\text{m}$ ). Between these regions of absorption, there are substantial 'window' regions, which are free from interference by carbon dioxide and water, and which can be used for remote gas sensing. Since the amount of water vapor in the atmosphere varies, it is necessary to take great care with measurements made close to the edges of these window regions.

Table 1 lists some of the gases that can be observed in the 'window' regions of the atmosphere. It shows that a large number of target gases can be detected by remote gas-sensing systems that are capable of operation at the correct wavelengths.

Gas absorptions in the ultraviolet are due to electronic transitions in the target species and are relatively strong. They lead to well-defined line spectra that allow gases to be detected with considerable sensitivity. When combined with the use of detectors with near-quantum limited performance this leads to detection sensitivities of a few nanomoles per mole over typical path lengths.

The strongest infrared absorptions are due to the fundamental vibrations of molecules, and are mainly at wavelengths longer than 2.5  $\mu\text{m}$ . These are usually in bands of lines at approximately equal spacing. Weaker 'overtone' bands occur at shorter wavelengths. It is also possible to carry out remote gas sensing in the microwave region. The performance of detectors in these regions is poorer than in the ultraviolet. Consequently, remote gas sensing in the infrared is generally less sensitive than the ultraviolet or visible spectral regions and typical detection sensitivities are of the order of a few micromoles per mole over typical path lengths.

## Sensitivity and Specificity

The key characteristics of all remote gas-sensing systems are defined by a combination of the specifications of the apparatus (e.g., transmitter and receiver performance), the target species (e.g., absorption strength and bandwidth), and the atmosphere (e.g., interfering species and atmospheric attenuation). Knowledge of all of these leads to the definition of a number of parameters that characterize the method.

The first of these is the sensitivity. This expresses the minimum detectable concentration (often as a function of range) and is usually quoted in the absence of interference. It is defined mathematically by equating the product  $\alpha C$  with the noise level of the system. It is usually stated in units of path-integrated concentration, most correctly in units of  $\mu\text{g m}^{-2}$ , or alternatively in ppm m (where ppm is used to express the partial pressure of the target species as millionths of the total atmospheric pressure).

A specification of range-resolved remote gas-sensing systems that is closely related to the sensitivity is the maximum range. This is simply the range at which the sensitivity passes some defined threshold, such as the path-integrated concentration being equal to a stated value.

The second parameter used to specify the performance of a remote gas-sensing method is the specificity (or selectivity). This expresses the ability of the method to measure the target in the presence of other species. It is defined mathematically by equating  $\alpha C$  to  $A$ . The specificity will usually be expressed in the same units as the sensitivity.

This short discussion shows that the key parameters used to characterize the performance of a remote gas-sensing method are closely related to those used to characterize any spectroscopic instrument together with the added feature that the performance of a remote gas-sensing system is also related to the range over which the measurement is made.

## Types of Remote Gas-Sensing System

The emphasis of this overview has been on characterizing a remote gas-sensing system in terms of its sensitivity and specificity. It is also possible to group systems according to their mode of operation.

The capability of a system to measure a range of different species is determined by its ability to operate at different wavelengths. Single-wavelength systems (e.g., DIAL) are usually capable of measuring a single species, although they can sometimes operate with a wavelength tunable source to measure additional species. Multi-wavelength systems (e.g., DOAS and FTIR) operate over a wide wavelength

range and are intrinsically able to measure more than one species simultaneously.

Remote gas-sensing systems can also be grouped according to the type of equipment used at the 'remote' end. For example, double-ended systems, such as DOAS, have a remote source, while TDLAS is often operated with a remote reflector or detector. The principal example of a single-ended system is DIAL, which depends on atmospheric backscatter and therefore has a single apparatus that includes both the transmitter and the receiver.

## Advantages and Disadvantages of Remote Gas Sensing

Calculated values for the sensitivity and specificity of remote gas-sensing systems will generally appear to be poorer than many point sensing methods that are also less complex and available at lower cost. However, they must be judged on the basis of their capability to carry out measurements that are not readily performed using point sensing methods, for example:

- Remote gas sensing results represent a spatial average over an extended path. This may be extremely useful when concentrations vary spatially or temporally, or when the point concentration is too low to be detected directly, but the integrated-path concentration is above the detection threshold.
- The results of remote gas-sensing measurements can be used to estimate a flux of the target gas across the measurement path.
- Measurements can be made along a path that cannot be accessed directly. This could include passing through regions that are hostile because of high temperatures or pressures or have high concentrations of corrosive or toxic gases, for example, in measuring across emission sources such as stacks.
- Appropriate movements of the measurement path can lead to the development of a two- or three-dimensional map of the target species. In this way, a remote gas-sensing system may be able to replace several monitors carrying out point sensing.
- In an extension of the principle of mapping, a well-chosen path for the beam may have a greatly increased probability of locating emissions from a source whose location is not known.

There are some general limitations of remote gas sensing; the cost and complexity of remote gas-sensing monitors is often much greater than point monitors, which do not have the advantages listed above. This is not always the case for remote gas-sensing monitors designed for very specific measurements of a single gas, but is usually the case for monitors with

the capability to measure more than one species. Finally, there are some complex issues relating to the calibration and validation of remote gas-sensing methods that are discussed below.

In general, remote gas-sensing methods cannot match the sensitivity of similar techniques deployed with long pathlength cells under laboratory conditions. Similarly, they cannot match the specificity of the best nonoptical techniques (e.g., gas chromatography or mass spectroscopy).

## Calibration

The acceptance of any monitoring method into the widest range of applications is not dependent solely on its principle of operation, but also on the demonstration and widespread recognition that the data it produces are valid. This is usually achieved by operating within a recognized quality assurance regime together with the use of an appropriate calibration procedure.

In the early applications of remote gas-sensing systems, great emphasis was placed on the fact that they operated according to a well-validated 'law' of physics and consequently it was claimed that they were 'self-calibrating' when used with valid spectroscopy for the target species. Although, there is some truth behind such statements, they do not provide sufficient transparency to nonexpert users of the data to gain the acceptance of standards-making bodies. In particular, issues such as the bandwidth of the source, spectral interference, nonlinearity of the detector system, and all other wavelength-dependent effects in the optical system itself undermine this simplistic claim.

Direct calibration of the performance of a remote gas-sensing system can be achieved by placing a cell containing a known concentration of the target species in the path. This approach has been demonstrated in practice for all of the methods discussed here, but is limited by the practical difficulties of making a cell with windows that are completely transparent at the measurement wavelengths.

Although the principle of calibration of remote gas sensing monitors is straightforward – if inconvenient, a further difficulty lies with establishing the 'zero' level for the measurement. This is readily achieved in point-sensing instruments by flushing them with

'zero gas', but this is not possible for any instrument operating over an extended atmospheric path since it can never be assumed that the target species or an interfering species are not present. Alternative approaches to resolving this problem are by switching to a shorter or clearer path. It should be noted that DIAL, which intrinsically measures the concentration gradient and those methods that use spectral background fitting, such as DOAS and FTIR, do not have this drawback.

## Selected Applications

Remote gas-sensing methods have been demonstrated to be highly effective in a large number of applications. These include:

- direct measurements of gas fluxes from a wide area,
- the generation of two- or three-dimensional concentration maps of target gases,
- scanning along a line or across an area to provide an 'alarm'-type warning of the buildup of toxic or flammable gases,
- monitoring of gas concentrations at the boundary of an industrial plant in order to identify significant direct or fugitive emissions from the area,
- measurements along elevated paths, including measurements at heights substantially above ground level, and
- measurements of the lower and middle atmospheres from satellites.

## Introduction

Integrated-path remote gas sensing is the process of measuring, or detecting, a target gas along an open

path defined between a transmitter and a receiver. The quantity measured by integrated-path gas sensing is the path-integrated concentration defined as  $\int \alpha C(r') dr'$ , where  $C(r')$  is the concentration at range  $r'$  and  $\alpha$  is the absorption coefficient at the wavelengths of the radiation used.

The simplest methods for integrated-path remote gas sensing use a receiver and a remote source of radiation as a transmitter. The measurement path is defined between the transmitter and the receiver. A simple development is through the use of a remote reflector (either a plane or a retro-reflecting mirror) to return the radiation to the receiver. The transmitter and receiver can then be co-located. In this configuration, the measurement is made over the return path between the transmitter and receiver.

Four different methods used for integrated-path remote gas sensing are discussed here. One of these (tunable diode laser absorption spectroscopy, TDLAS) uses a narrow linewidth source of radiation (usually a laser diode) and the other three methods use broadband sources of radiation. These three analyze the spectrum of the radiation after it has traversed the atmospheric path in different ways: both differential optical absorption spectroscopy (DOAS) and Fourier transform infrared (FTIR) spectroscopy analyze the entire spectrum over the spectral region of interest, whilst absorption correlation methods record the spectrum after it has been filtered optically with either an optical filter or a sample of the target gas itself. These four methods use an 'active' source of radiation. It is also possible to carry out integrated-path remote gas sensing using a 'passive' source.

Integrated-path remote gas sensing methods are the most widely used of all methods for remote gas sensing. This is because they have greater sensitivity than range-resolved methods since the signal strength is substantially higher. Consequently, they can be used with lower-powered sources than range-resolved remote gas sensing systems and are therefore less costly and complex.

## Tunable Diode Laser Absorption Spectroscopy

Many of the first demonstrations of remote gas sensing used integrated-path absorption usually in conjunction with a laser source. Examples included helium–neon, argon-ion, and carbon dioxide lasers. Subsequently, some successful practical devices were also made that used incandescent sources. However, the small size and high efficiency of diode lasers have given them a major application in this field as is reflected in the description 'TDLAS'.

In recent years, the field has been dominated by the use of tunable diode lasers. Initially, tunable cryogenic lead-salt diodes were used because they were the only practical means of providing tunable continuous-wave radiation in the infrared spectral region where many of the most important target gases absorb. More recently, distributed-feedback and grating-tuned diodes have become widely available at wavelengths close to the telecommunications bands in the near-infrared. In the future, it is expected that quantum cascade lasers, which are capable of tunable operation at wavelengths longer than 5  $\mu\text{m}$ , will find applications in integrated-path remote gas sensing.

An important part of the operation of any integrated-path remote gas sensing method is that in order to achieve a quantitative measurement that is distinct from the background signal, it is necessary to impose some form of modulation on the source radiation. The simplest way to do this is to choose two wavelengths, one of which is strongly absorbed by the target species and the other is not. Since the absorption of the target gas changes with wavelength, the intensity of the beam traversing a path containing the target will also vary as the wavelength changes.

A more sophisticated method is to modulate the wavelength of the beam such that the intensity of the measured signal is modulated at the same frequency. Some type of data processing can then make use of the modulation signal to recover this part of the measured intensity. More sophisticated versions of this approach make use of detection at the second or higher harmonics of the modulation frequency.

Figure 1 shows a schematic diagram of an example of a TDLAS system. The source is shown together with a chopper to modulate the transmitted radiation. It is usually possible to do this directly, in which case the chopper is not required. A retro-reflector is used to return the beam to the monitor and a gas cell

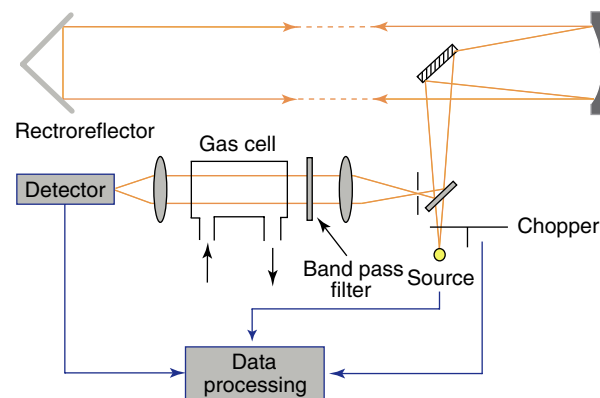

Figure 1 Principal components of a TDLAS monitor.

is shown that can be used as part of a calibration procedure.

The most common application of TDLAS is to the measurement of methane. This has been extremely successful, because methane has a well-defined line spectrum and is detected at high concentrations, usually close to its flammability limit.

## Differential Optical Absorption Spectroscopy

The TDLAS method described above uses differential absorption or wavelength modulation and operates over a narrow spectral region. In contrast, the DOAS method employs a broadband source and a spectrometer within the receiver to disperse the returned signal prior to detection. Consequently, a much larger spectral range including many spectral lines can be measured and a number of different target gases can be measured simultaneously. **Figure 2** shows a schematic diagram of a DOAS system. This example uses a polychromator together with a photodiode detector array.

DOAS systems are usually operated in the ultraviolet or visible spectral regions where high-intensity sources (such as xenon arcs) are available. In some applications to atmospheric measurements, very high sensitivity is achieved by using a measurement path through the whole atmosphere with the sun acting as the source. Radiation is dispersed by the spectrometer and detected in such a way that a complete spectrum of the source, as modified by absorption along the atmospheric path, is recorded. The spectrum is scanned repetitively, with each scan taking less than  $\sim 10$  ms in order to avoid significant intensity changes caused by atmospheric turbulence during the scan. Successive scanned spectra are then added over a predetermined time period and stored. The resulting atmospheric spectrum is fitted to the stored

spectra of the target gases, using a least-squares fitting method, in order to obtain the best estimate of the concentrations of any target gases present in the atmosphere. The spectrum of the source itself and the influence of other atmospheric effects are removed during the data processing using a similar spectrum taken over a very short optical path or by fitting a low-order polynomial curve to establish the background. The residual deviation between the fitted and recorded spectra gives a measure of the uncertainty in the determination of each target gas.

The DOAS technique has been used extensively in the ultraviolet and visible spectral regions for measurements of gases including sulfur dioxide, nitrogen dioxide, ozone, methanol, and aromatic compounds at  $\text{nmol mol}^{-1}$  levels and at distances of up to 1 km. It has even been used, in modified form, to measure concentrations of the OH radical, which is important in studies of atmospheric chemistry, but is only present at very low concentrations.

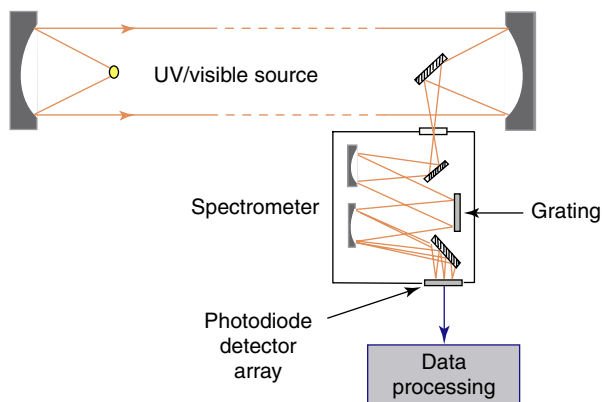

## Fourier Transform Infrared

The general principle of operation of the FTIR method is similar to the DOAS method, because they both measure and analyze over a broad region of the spectrum. The principal difference is that an FTIR spectrometer is used instead of a conventional dispersive monochromator. The benefits of using an FTIR in place of a monochromator can be summarized in terms of two types of advantage:

- Radiation from the entire spectrum is sampled throughout the measurement period; in general the duration of the measurement period limits the resolution of the measurement and not the spectral range.
- A much larger optical throughput is possible than with a dispersive monochromator with the same resolution, hence the signal-to-noise ratio is larger.

Long-path FTIR monitors are usually used in a 'bistatic' configuration with a source at the far end of the measurement path. Alternatively, the sun can be used as the source in order to allow the measurement of gases at any altitude along the atmospheric path between the sun and the observer. This approach is usually used to measure stratospheric gases from a site on the ground or from an aircraft, balloon, or satellite.

**Figure 3** shows the principal components of an integrated-path FTIR monitor. The absorption spectrum of the atmosphere within the band pass of the filter over the measurement path is recorded by the Michelson interferometer. This spectrum is then used

**Figure 2** Principal components of a DOAS monitor.

**Figure 3** Principal components of an FTIR monitor.

to identify and quantify any target gases by reference to their component spectra in the total spectrum. Early FTIR monitors used high spectroscopic resolution (typically  $0.05\text{ cm}^{-1}$ ) to record spectra with sufficient resolution to resolve the narrowest atmospheric lines completely. More recently, systems with lower resolution (typically  $1\text{ cm}^{-1}$ ) have come into use because they have sufficient spectroscopic resolution to achieve the accuracy required in most applications and allow the use of more compact and lower-cost FTIR spectrometers.

Multiple-species measurement in near real-time is possible with FTIR systems by comparing the atmospheric spectra obtained with stored spectra of a range of possible gases, using a 'least-squares' approach. Gas concentrations of tens of  $\text{nmol mol}^{-1}$  are typically measurable over paths of a few hundred meters. However, there can be problems of interference from other atmospheric species (especially water vapor) and due to the failure of Beer's Law because of the limited spectral resolution. These make it difficult to fit stored spectra accurately and automatically, and skilled operator intervention is generally required.

Integrated-path FTIR systems have been used for a variety of applications, including monitoring of volatile organic compounds from industrial plant, monitoring toxic and irritant gases in urban areas, and measuring gas release rates from coal mines and landfill sites.

## Absorption Correlation Spectroscopy

Absorption correlation spectroscopy works by making a real-time comparison between a portion of the atmospheric absorption spectrum and the absorption of a sample of the target gas itself. This contrasts with the DOAS and FTIR methods, which record the same type of spectrum over the atmospheric path, but recover the concentration of the target gas mathematically by reference to known spectra of the pure target gas. Two correlation methods are in use.

In 'dispersive correlation spectroscopy', radiation that has traversed an atmospheric path is dispersed by a monochromator. The spectrum is dispersed spatially onto a rotating disk with a series of slits. This disk contains in one-half slits that have been cut at points that correspond to wavelengths at which the target gas has absorption maxima, and in the other half slits at points where the target gas has absorption minima. A detector behind the disk collects the transmitted radiation. By evaluating the correlation between the signals from the two portions of the disc the analyzing electronics produce an output that is sensitive to the target gas but relatively insensitive to any other gases.

In 'gas filter correlation spectroscopy', the spectrometer and rotating disk are replaced by a cell containing a sample of the target gas at a known concentration (or by a pneumatic detector containing the target gas). Radiation traversing the atmospheric path then passes through either the cell of target gas or a similar empty cell, both followed by a detector. If any target gas appears in the atmospheric path then the detector signal for radiation that has passed through the empty cell will be correspondingly diminished. However, the signal from the radiation that has been passed through the target gas cell will not be reduced as much because the intensity at the principal wavelengths absorbed by the target gas along the atmospheric path will have been reduced. Subtraction of the target gas signal from the empty cell signal then gives an output that is sensitive to the target gas but insensitive to other gases.

Gas filter correlation is more attractive than dispersive correlation because it does not require a monochromator or a chopping disk with a specific slit pattern. Furthermore, it performs its correlation with the actual gas itself, giving a near ideal correlation between the target gas in the atmosphere and the cell. This technique is commonly known as non-dispersive infrared (NDIR) measurement, since there is no spatial dispersion of the wavelengths in the gas-analyzing beam. The principal components in an integrated-path gas correlation monitor are shown in Figure 4.

Both correlation methods require a target gas with a distinctive narrow-line spectrum, which restricts them largely to diatomic and triatomic species. The less specific the spectrum, in terms of the presence of well-defined spectral lines, the more interference will be caused by other gases.

The main advantages of gas correlation monitors are that they are relatively simple and can be constructed at low cost. They use a single detector for each gas and have good discrimination against other gases if the target gas has a distinctive spectrum.

**Figure 4** Principal components of a nondispersive gas correlation monitor.

Although they can be set up to monitor several gases by splitting the radiation into several different paths, they are generally only used to monitor one target species without modification of the correlation element.

NDIR are much used in the laboratory and in industry over short gas paths for gas concentration measurement. Recently, they have been applied to the longer paths required for 'stack gas' monitoring and the much longer paths (hundreds of meters) required for ambient air monitoring. Measurements of gases such as methane, ethane, hydrochloric acid, carbon monoxide, and carbon dioxide have also been demonstrated at industrial sites and roadsides.

## Passive Methods

All of the methods discussed above are described as 'active' because they make use of an 'active' source of radiation as part of the system. It is also possible

to measure gases remotely using passive methods that detect radiation emitted thermally by the target gas itself or by other objects within the field of view. Examples of this type of system are sensors used with a small number of spectral channels mounted on satellites and used to carry out qualitative identification of features on the earth's surface, such as vegetation or mineral species. Hyper-spectral imagers with a large number of spectral channels are capable of better qualitative measurements of the composition of objects in the field of view or along the measurement path. However, the derivation of true quantitative results from such instruments is problematic because of the difficulty of obtaining accurate information about the emissivity of the objects and their temperature. Nevertheless, this type of approach holds much promise for future development.

## Introduction

Range-resolved remote gas sensing is the process of simultaneously determining the concentration and distribution of a target species at locations remote from the measurement system using a single measurement. The range-resolved remote gas sensing methods that have been demonstrated successfully use pulses of optical radiation that are selectively absorbed or scattered by the target species. The range information is recovered by timing the propagation of the pulse to the absorbing, or scattering, event.

Another feature of these techniques, which is implicit in their ability to provide range information, is that they can operate from a location that is remote from the point being measured. They are distinguished from integrated-path remote gas sensing (q.v.) techniques, which are capable of performing remote measurements but are not capable of recovering information about the distribution of the target species along the measurement path.

Range-resolved gas sensing techniques have many advantages over the more widely used point-sensing methods. They are capable of scanning many locations and acquiring data that would require many individual point sensors. The addition of range information to concentration measurements enables maps of gas concentration to be compiled. The flexibility of range-resolved remote gas sensing has

**Figure 4** Principal components of a nondispersive gas correlation monitor.

Although they can be set up to monitor several gases by splitting the radiation into several different paths, they are generally only used to monitor one target species without modification of the correlation element.

NDIR are much used in the laboratory and in industry over short gas paths for gas concentration measurement. Recently, they have been applied to the longer paths required for 'stack gas' monitoring and the much longer paths (hundreds of meters) required for ambient air monitoring. Measurements of gases such as methane, ethane, hydrochloric acid, carbon monoxide, and carbon dioxide have also been demonstrated at industrial sites and roadsides.

## Introduction

Range-resolved remote gas sensing is the process of simultaneously determining the concentration and distribution of a target species at locations remote from the measurement system using a single measurement. The range-resolved remote gas sensing methods that have been demonstrated successfully use pulses of optical radiation that are selectively absorbed or scattered by the target species. The range information is recovered by timing the propagation of the pulse to the absorbing, or scattering, event.

Another feature of these techniques, which is implicit in their ability to provide range information, is that they can operate from a location that is remote from the point being measured. They are distinguished from integrated-path remote gas sensing (q.v.) techniques, which are capable of performing remote measurements but are not capable of recovering information about the distribution of the target species along the measurement path.

Range-resolved gas sensing techniques have many advantages over the more widely used point-sensing methods. They are capable of scanning many locations and acquiring data that would require many individual point sensors. The addition of range information to concentration measurements enables maps of gas concentration to be compiled. The flexibility of range-resolved remote gas sensing has

provided a way to study complex atmospheric transport processes and to locate and quantify industrial emissions.

## The LIDAR Principle

The methods that have been successfully used for range-resolved remote gas sensing all use the principle of light detection and ranging (LIDAR) to achieve range resolution. The LIDAR principle is the optical analog of radar (radio detection and ranging). It depends on the accurate timing of a pulse of radiation from a transmitter to a scattering event and back. The range is then calculated by converting the time of flight to a distance using a value for the speed of light. A schematic diagram of the major components in a LIDAR system is shown in Figure 1. The transmitted and received beams are usually directed into the atmosphere with a steering mirror in order to alter the direction in which the system measures.

The energy recorded at a detector collecting light from a telescope of area  $a$  from the transmission of a pulse of energy  $E$  is given by

$$P(r) = E\eta \frac{a}{r^2} B(r) \exp\left(-2 \int_0^r [A(r') + \alpha C(r')] dr'\right)$$

where  $B(r)$  and  $A(r)$  are the backscatter and absorption coefficients of the atmosphere, respectively, and  $C(r)$  is the concentration of the target species of absorption coefficient  $\alpha$ .

The difference between the various range-resolved remote gas sensing methods is in the nature of the processes used to return the light to the receiver. There are three processes that have been demonstrated

thoroughly: fluorescence, Raman scattering, and differential absorption combined with elastic (either Mie or Rayleigh) scattering.

Fluorescence has been used effectively in specialized applications (e.g., the measurement of the hydroxyl ion at short distances from airborne platforms) but it has not been applied widely to analytical measurement problems. Similarly, Raman scattering has been used in particular applications (e.g., the measurement of water vapor at high altitudes and the measurement of high concentrations of methane close to ground level). The cross-sections for fluorescence and Raman scattering are very low compared with elastic scattering, so they have only been used when there are specific reasons why the differential absorption and scattering method is not applicable. Additionally, they require either some form of spectral dispersion (in the case of Raman) or time gating (in the case of fluorescence) in order to distinguish them from the elastic scattered return.

The remainder of this article is devoted to the differential absorption LIDAR or DIAL method that is the most widely used technique for range-resolved remote gas sensing. It relies on elastic scattering from small particles and molecules that are always present in the atmosphere to return the signal. Speciation is achieved using the principle of differential absorption as described below.

## Differential Absorption LIDAR

The DIAL method makes use of two LIDAR measurements performed within a very short time interval at two different wavelengths. One is chosen to be at a wavelength that is absorbed by the target gas. The

**Figure 1** Schematic diagram of a differential absorption LIDAR (DIAL) system.

other is at a wavelength that is not absorbed by the gas of interest and forms a reference channel that measures the 'background' properties of the atmosphere.

The unknown concentration is then determined by taking the ratio of the returned intensity at the on-resonant wavelength ( $P_{\text{on}}$ ) to the off-resonant wavelength ( $P_{\text{off}}$ )

$$\log[P_{\text{on}}(r)/P_{\text{off}}(r)] = - \int_0^r (\alpha_{\text{on}} - \alpha_{\text{off}}) C(r') dr'$$

where  $\alpha_{\text{on}} - \alpha_{\text{off}}$  is the differential absorption coefficient between the on- and off-resonant wavelengths. If the absorption coefficient of the gas is known, then the concentration can be determined by calculating the ratio of the returned signals from the two measurements. Since both the measurements are time-, and hence range-resolved, it is possible to identify the distance to the point at which the concentration was measured. Performing this calculation at all ranges along the signal yields the concentration as a function of distance along the path of the measurement beams.

It is often stated that the principle of operation of LIDAR leads to a range resolution for the measured profile equal to half the length of the pulse. Although this is true for systems with long pulses and high-speed detectors, it is generally not true for systems using laser pulses with durations less than 50 ns. In typical examples of the DIAL technique, usable results can be achieved with range resolutions of several tens of meters achievable at ranges of many kilometers.

The species that can be measured by DIAL are most easily categorized according to the wavelength region of the radiation that is used to measure them. Examples of the species that can be measured by DIAL using presently available technology are shown in Table 1. Each of the wavelength regions listed in Table 1 requires a different type of laser transmitter and receiver system. These differences are sufficiently large that DIAL systems are usually designed to operate in just one wavelength region. Consequently,

each of these regions has become associated with particular choices of technology and applications.

## Applications of DIAL in the Ultraviolet and Visible Spectral Regions

High-quality components required for a DIAL system in the 220–900 nm spectral region are more readily available than those needed in other spectral regions. Excimer and solid-state lasers have sufficient pulse energies (in excess of 500 mJ), pulse lengths (between 5 and 50 ns), and repetition rates (between 5 and 100 Hz) for use as primary sources of laser energy. They can be used to pump tunable dye lasers or tunable solid-state lasers that can be used in conjunction with nonlinear optical techniques to generate the correct wavelengths in the ultraviolet and visible. Detectors such as photomultipliers and avalanche photodiodes which are capable of single-photon detection are available. The availability of suitable laser and detector technologies together with the strong backscattered signals from Rayleigh scattering led to this being the first region in which effective DIAL applications were demonstrated. The most important applications of DIAL in the ultraviolet and visible spectral regions include:

- studies of the movement of ozone within the stratosphere and troposphere;
- the monitoring of the dispersion of sulfur dioxide and nitrogen dioxide from industrial stacks;
- measurements of fugitive emissions of benzene, toluene, and xylene from chemical and petrochemical plants; and
- profiles of water vapor in the troposphere and lower stratosphere from ground-based and airborne platforms.

## Applications of DIAL in the Near-Infrared

The near-infrared between 2 and 5  $\mu\text{m}$  is perhaps the most technically challenging spectral region in which to perform measurements by DIAL. This is in part because of the weak and variable Mie scattering from particles at these wavelengths. Additionally, there are no simple primary laser sources available so the techniques of nonlinear optics must be used in order to generate suitable narrowband radiation. These include difference frequency mixing between fixed and tunable sources in the visible spectral region and the use of tunable optical parametric oscillators. These technical difficulties are well worth overcoming

**Table 1** Gases that can be measured using the DIAL technique

Wavelength range	Species measurable
220–900 nm	SO <sub>2</sub> , O <sub>3</sub> , NO, NO <sub>2</sub> , Hg, benzene, toluene, xylene, H <sub>2</sub> O
2–5 $\mu\text{m}$	Methane, alkanes, alkenes, alkynes, CO, HCl
9–11 $\mu\text{m}$	Chlorinated hydrocarbons, SF <sub>6</sub>

because of the wide range of gases that can be measured (see Table 1. Applications include:

- the identification of fugitive emissions of hydrocarbon vapors in chemical plants and
- detection of the build-up of flammable gases in industrial areas.

### Applications of DIAL in the Mid-Infrared

The use of the DIAL method in the mid-infrared spectral region has arisen from the availability of the high-powered carbon dioxide laser and the wide range of species with absorption lines in the range 9–11  $\mu\text{m}$ . However, the carbon dioxide laser cannot be tuned continuously across the spectrum so it is not possible to use a single carbon dioxide laser to measure all the species that have absorption lines in this region of the spectrum. Possible applications include:

- monitoring for the build-up of toxic gases generated as industrial by-products and
- ‘early warning’ of the presence of chemical agents used in weapons.

### Range, Range Resolution and Accuracy

When all the parameters of a DIAL system are known, it is possible to perform calculations of the range, range resolution, and sensitivity in the measurement of a specific target gas. However, such calculations are complex and the results are strongly

**Table 2** Performance of a DIAL system. The typical sensitivity applies at half the maximum range and the stated range resolution. The maximum ranges refer to analog detection. In some applications in the 220–900 nm region, they may be extended to 25 km using photon counting techniques

Wavelength range	Maximum range	Range resolution	Typical sensitivity
220–900 nm	1–3 km	10 m	1 ppb
2–5 $\mu\text{m}$	500 m to 1 km	15 m	100 ppb
9–11 $\mu\text{m}$	1–10 km	100 m	50 ppb

dependent on the exact measurement scenario and atmospheric conditions. A summary of typical performance in each spectral region is presented in Table 2.

### Introduction

Nowadays, trace element determinations are performed using very sensitive analytical techniques. However, with a lowering of detection limits, the risk of errors suddenly appearing due to sample handling is increased. Prior to commercial introduction of ultrasensitive instrumentation as inductively coupled plasma-mass spectrometry (ICP-MS), these 'new' errors were practically imperceptible to the determination of relatively high analyte concentrations that were measured with less responsive techniques. The danger of contamination is now increasingly present: the choice of sample preparation procedure, the quality of its application, and the need for an adequate laboratory environment have therefore become most critical points defining successful trace element determinations.

In most cases, preparation of solid samples involves several stages: drying, homogenization, and/or grinding, followed by mineralization and dissolution of a subsample. The solution so obtained is ultimately diluted to volume. Ideally, the organic fraction of the sample has been decomposed and completely eliminated during these preparation steps and only dissolved inorganic compounds constitute the dissolved residue to be analyzed.

Before the analysis, samples of organic or of a mixed nature are subject to two distinct steps, which often take place simultaneously: mineralization and dissolution. Samples of purely inorganic composition are simply dissolved. The composition of biological and environmental samples varies from purely inorganic to purely organic, but, generally, they are an intermediate combination of these extremes. This implies that the total dissolution of samples usually cannot be achieved in a single step using a single reagent. In practice, the necessary number of steps and reagents is dictated by the matrix composition. Purely organic or mixed samples are usually brought into solution by some type of oxidation process combined with an acid dissolution of the resulting residue, as well as of the initial inorganic part of the matrix.

Already in 1844, Fresenius and Von Babo had developed a method for the destruction of animal tissues prior to elemental analysis. In the intervening years, many procedures were described for this purpose. However, despite numerous possible variations, almost all of the methods fall into one of two main classes, i.e., dry ashing and wet digestion. Dry ashing methods are especially appropriate for samples having high organic matter content. The first step of the method ensures the decomposition of organic matter by heating the sample to a relatively high temperature, with atmospheric oxygen serving as the oxidation agent. Chemical compounds (the so-called ashing aids) may sometimes be added to help this process. The second step of a dry ashing method is the subsequent solubilization of the resultant ash using an appropriate acid or a mixture of acids.

Depending on the sample type, the dissolution procedure generally involves several steps. Here, the terminology is precise: the term 'mineralization'

relates to samples having a totally or partly organic matrix only (animal and plant tissues, food samples, soils, etc.). Prior to the analysis, any organic compounds present must be decomposed and/or completely eliminated by the mineralization procedure. Using various reagents, the organic matter is decomposed into carbon dioxide, nitrogen oxides, and water, thus liberating into solution all elements initially associated with it. After the mineralization procedure, the resulting sample residue should be essentially inorganic: it will be subject to a final dissolution step similar to that used for a sample having an initially total inorganic composition (rocks, metals, etc.). For more complex samples (organic plus inorganic composition: soils, sludge, plant samples, etc.), chemical reagents and physical means are most often used to ensure these two roles (mineralization and dissolution) are simultaneously achieved.

The objective of the sample preparation stage is usually to bring all available means into play in order to determine as readily as possible the elements of interest. First, these means have to ensure the transformation and simplification of the matrix (mineralization: wet digestion, dry ashing). Second, they should convert the sample to a form compatible with the measurement technique utilized (generally a dissolution).

Dry ashing methods compete with the following techniques for sample dissolution of organic and biological species for elemental analysis:

- wet ashing in open or closed vessels,
- oxygen flask techniques,
- combustion tube techniques, and
- microwave digestion techniques in open or sealed vessels.

## General Principles

After the appearance, at the end of the 1970s, of commercial advertisements praising the universality and absolute necessity of wet digestion microwave heating devices for trace element analysis, several scientific papers have radically condemned dry ashing procedures, despite their long record of usefulness. In contrast, many respected institutions as well as numerous laboratories carry on the use of classical dry ashing in practical analyses of a number of materials of biological origin.

Our own extensive experience in the field of sample preparation has shown that, better than the other known mineralization procedures, dry ashing methods ensure the quantitative decomposition and elimination of organic matter. Usually, these procedures

are performed by calcination at atmospheric pressure in programmable muffle furnaces. The commonly utilized temperature for this step is  $\sim 450^{\circ}\text{C}$ . In addition to conventionally heated muffle furnaces generally employed for dry ashing purposes, the market now also provides microwave furnaces especially adapted to attain elevated temperatures. The unique advantage of the latter is the capacity to ensure application of very fast heating ramps. However, this property is not directly interesting for usual dry ashing procedures, where precisely slow heating ramps are needed. Additionally, a low-temperature ashing (LTA) procedure in electronically excited oxygen plasma exists, very desirable for sample preparation when volatile elements are to be determined. The instrumentation is, unfortunately, very expensive and not readily available at present. In addition, LTA is a particularly time-consuming procedure.

In the usual high-temperature ashing, fresh or dried (generally  $103\text{--}105^{\circ}\text{C}$ ) samples are weighed into suitable ashing vessels (vitreous silica, porcelain, platinum) and placed in the furnace. The temperature is then progressively elevated, following a convenient heating program, to attain  $450^{\circ}\text{C}$ , and then maintained for several hours. The resulting inorganic residue (ash) is dissolved using an appropriate acid. The solution is diluted to a known volume and analyzed. Depending on the initial sample condition, results are expressed based on a fresh- or dry-weight basis. The application of dry ashing methods is simple and large series of samples may be treated at the same time. This is not their unique advantage – compared with wet digestions, dry ashing procedures present several other interesting characteristics:

1. Possibility of treating large sample amounts and dissolving the resulting ash in a small volume of acid. This permits preconcentration of trace elements in the final solution, which is useful when very low analyte concentrations are to be determined. Such an advantage is not realizable with wet digestion methods. Additionally, heterogeneity is a typical property of many biological materials. The possibility of processing larger masses of sample, which, upon mineralization, provides a homogeneous solution, helps to minimize subsampling errors.
2. The resulting ash is completely free of organic matter. This is a prerequisite for ensuring accuracy with some analytical techniques (e.g., ICP-MS or electrochemical methods) wherein analyte response may be influenced by the presence of residual carbon or some undigested organic molecules. The resulting solutions are of very acceptable aspect

(clear, colorless, and odorless), rarely the case when wet digestion methods are used and residual carbon content often attains elevated values. This is systematically observed not only for both conventionally heated and open microwave digestions, but also for closed microwave-assisted digestions. With high-pressure bombs, the residual carbon content may be lower but it is never quantitatively eliminated.

3. Reagent volumes and their handling are reduced compared to wet digestion methods.

4. The acidity of final solutions can efficiently be controlled: the acid is added directly to the ash and only a small fraction is consummated during its dissolution. With wet digestion procedures, added acids must also ensure the destruction of the organic matter and their effective amounts utilized during these chemical reactions vary quite significantly. This results in unknown acid concentrations in the final solutions to be analyzed. This fact is at variance with well-known requirements for all methods based on atomic spectroscopy concerning the need for similarity of acidities between standards and samples. In some situations, this similarity is absolutely obligatory, e.g., for the determination of nickel by ICP-MS. The commonly used nickel cones in the ICP-MS interface usually produce relatively high nickel backgrounds due to their finite dissolution by the aerosol being introduced. With variable acid concentrations, the background can vary significantly from one sample to another, resulting in erratic nickel results. Such unfavorable conditions are avoided using dry ashing methods that ensure a practically constant acid concentration from sample to sample, allowing more consistent ICP-MS determinations of nickel to be made.

Despite these several advantages, one must also accept several drawbacks to dry ashing procedures:

1. The chemistry of charring process is very complex and the actual temperature in the sample remains unknown; in some cases, it may be several hundred degrees above that of the furnace. This may result in volatilization losses and then to poor recoveries of some elements.

2. Under particular experimental conditions and for some types of samples, retention phenomena can occur, resulting also in incomplete recoveries.

3. Dangers of contaminations by the ambient air are greater than in wet digestion procedures performed in closed systems.

### Chemistry of the Method

Results of studies concerning the dynamics and chemistry of organic matter degradation revealed

the strong exothermic character of decomposition during charring but also a possible variability, depending on the specific type of biological material. The former findings call for sufficient moderation of the charring step (ramp heating) in order to prevent local overheating of the sample and subsequent risk of loss of a fraction of the analyte due to its mechanical removal in the form of solid particles of aerosol (smoke). Only under such controlled conditions can classical dry ashing have the potential to yield accurate results.

The term 'dry oxidation' usually characterizes procedures wherein organic matter is oxidized by reaction with gaseous oxygen, generally with the supply of energy in some form. Included in this general term are methods in which the sample is heated to a relatively high temperature in an open vessel (conventional dry ashing), or in a stream of oxygen or air. In addition, related low temperature techniques employing excited oxygen, bomb methods using oxygen under pressure, and the classical oxygen flask technique in which the sample is ignited in a closed system must also be included. All these methods involve two main processes: they provoke evaporation of the moisture and of volatile materials and ensure the progressive oxidation of the nonvolatile residue until all organic matter is destroyed.

Although these processes occur in all dry oxidations, it is not always possible to distinguish them as separate events. They are probably most easily separated in the conventional ashing procedure in which the organic material is heated in an open vessel with free access to air or oxygen. In usual analytical practice, the first steps of such a procedure are usually conducted at a temperature much lower than that used to complete the oxidation. This is largely to prevent the ignition of the volatile and inflammable material produced by the process of destructive distillation and partial oxidation, as this would lead to an uncontrolled rise in the temperature resulting in an increased danger of analyte losses.

### Volatility Losses

The long experience has repeatedly shown that the most severe element losses are systematically observed during the heating ramp, not as a consequence of too high final ashing temperature. An inadequate heating ramp may provoke the autoignition of the sample and the resulting rapid temperature increase results in volatilization losses. The most often utilized means of avoiding ignition problems is direct insertion of the sample into the cold muffle furnace, followed by heating with an appropriately slow ramp.

Before the last stage of the process – progressive oxidation of the nonvolatile residue – the material remaining after the preliminary treatment is a more or less porous mass of charred organic matter containing variable amounts of inorganic material distributed throughout it. In reality, this picture is highly variable and it will depend not only on the type and the composition of samples analyzed, but also on the action of possible reagents added that can change the initial chemistry of the process. Consequently, the kinetics of oxidation of such material will be dependant on the nature of the material itself, the inorganic substances it contains, and its particle size and porosity. Tentative findings derived from such reactions with pure carbon or graphite can only be applied with caution to the complex chars existing in dry ashing of real samples. The temperatures generally recommended for dry ashing are apparently low compared with those reported for the oxidation of graphite, but the chars produced are probably far more reactive due to unknown catalytic effects of the inorganic constituents present.

In dry ashing procedures used for the analysis of environmental or biological samples (animal and plant tissues, food samples, blood, milk, etc.), the final temperature is maintained for several hours. If the oxidation is achieved under optimal conditions, it leads to white or light gray colored ashes, easily soluble in acids. Sometimes, depending on the sample type, the oxidation of organic matter is not completely achieved; in this case, the ash exhibits darker spots (dark gray to black) attributable to insufficiently oxidized carbon. Because this phenomenon is always responsible for a difficult subsequent dissolution (often resulting in incomplete recoveries for several elements), such a residue must be re-treated using a few drops of nitric acid and briefly recalcined at the usual ashing temperature. After this treatment, ashes generally become clear and easily soluble.

During the oxidation process, the analyte(s) will behave in one or more of a number of ways. Ideally, they will quantitatively remain in the residue (ash) arising from the oxidation, and in a form in which they can be readily recovered, generally by a simple dissolution of the ash in an appropriate acid. Fortunately, for the usefulness of the method, this is the case for most analytes and samples. In some cases, a part (or the total) of the analyte may be converted to a volatile form that may escape from the vessel (i.e., volatilization losses) or may be combined with the vessel surface or with some components of the inorganic residue remaining after oxidation (i.e., retention losses). In practical trace element analysis, the most often reported volatilization losses pertain mainly to mercury, arsenic, and selenium.

## **Retention Losses**

Retention losses result in poor recoveries of one or more analytes using the normal procedure for solubilization of the ash. They are generally observed for a particular quality of ashing vessel or in the presence of silicates or other insoluble compounds in the sample matrix. During intercomparison studies involving analyses of plant matrices, significant discrepancies amongst results are often observed between laboratories using simple mineralization procedures and those that apply procedures that include a hydrofluoric acid attack followed by evaporation to dryness. In the former, the values obtained are systematically lower because complete digestion is not achieved. In the often utilized wet digestion procedures, mixtures of various acids with hydrogen peroxide may also lead to poor recoveries due to the presence of silicate compounds in the sample or to (co)precipitation phenomena. As a consequence, Al, Fe, Cu, and Mn, in particular, are not completely recovered, depending upon the specific plant matrix, probably related to the binding of analytes with the insoluble residue. Several authors have noted similar problems with agricultural matrices such as composts, animal meats, or brewers yeast.

These statements, among others, are supported by studies concerning retention losses occurring during dry ashing of plant samples. For several plants, analyses of insoluble residues have revealed that a significant fraction of elements (major, minor, trace) is retained, depending on the type of sample and the element studied. The most affected element is Al (sometimes up to 95% retained). Consequently, it is useful to use the recovery of aluminum as a marker for the procedure quality; if the Al recovery is incomplete, it may be concluded that the dissolution step was not performed under good conditions and that many other elements may be affected in a similar fashion.

For an efficient dissolution of the ash of samples with silicate compounds in the matrix, such problems highlight the absolute necessity of utilizing an HF step followed by evaporation to dryness if the objective is the determination of total element content. However, this problem, typically associated with plant samples, is similar when applying a wet digestion procedure: if an insoluble residue remains, an additional HF step, followed by evaporation to dryness, must also be performed.

Another example highlighting this problem is associated to ICP-MS interferences from residual silicon resulted in up to 30% positive bias in intensities from  $^{63}\text{Cu}$ ,  $^{65}\text{Cu}$ , and  $^{55}\text{Mn}$  derived from soil and sewage sludge digests, due to spectral interferences

from  $^{28}\text{Si}^{27}\text{Al}^+$ ,  $^{28}\text{Si}^{35}\text{Cl}^+$ , and  $^{28}\text{Si}^{37}\text{Cl}^+$ . In such a case, the interfering Si will be easily removed by the above-mentioned HF step.

Such a procedure is not always easy to achieve with most commercially available microwave heating (closed) devices and is, in any case, much more difficult to apply than with a dry ashing procedure. Finally, plants are often considered as purely organic samples with some trace elements present. It is clear that the aforementioned problem is comparable to that encountered in soil, sediment, sludge, and rock samples where silicon is typically the primary matrix element. In this case, however, all analysts are aware of the absolute necessity of dissolving the entire sample if the total analyte content has to be determined.

An additional retention problem encountered with dry ashing procedures is that posed by the sequestering action of some materials produced during ignition. The binding of iron by condensed phosphates produced by the action of heat on simple phosphates, or retention of several elements on silicate compounds present in the sample are the best known examples. Nevertheless, many studies in this field often present contradictory observations, illustrating clearly the complexity of the retention problems and the need for an adequate dissolution step. On the other hand, with the exception of arsenic and selenium, these considerations indicate that several losses reported as being due to volatilization were, in reality, due to retention problems.

## Methodology

Dry ashing methods can be applied to mineralization of organic materials, biological tissues, and liquids, plant, and foodstuffs, sludge, etc. Well mastered, they ensure total destruction of the organic matter; the associated elements are generally transformed to carbonate or oxide forms. At present, they are generally performed using fully programmable (ramp and holding times/temperatures) muffle furnaces characterized by an efficient temperature control and reproducible thermal programs. Required intermediate evaporations to dryness are usually achieved on sand baths or on hot plates.

It is mandatory to select an ashing temperature that ensures the quantitative decomposition of organic matter without partial or total loss of analytes by volatilization or by their incorporation into a residue, which is insoluble in usual reagents. The latter may result from formation of refractory oxides, from combinations with other sample constituents present, as well as from reactions with the walls of the crucible. As noted earlier, one

of the causes of losses during dry ashing procedures is the reaction of the analyte with some of the solid matter present in the system. In order for a reaction of this nature to constitute a problem, it is first necessary that it occurs to a significant extent and, second, that the product of the reaction be insoluble in the reagents generally used for dissolving the resultant ash. The solid matter available for such a reaction is generally the material of the ashing vessel and the residue from the sample itself. It is obvious then that their nature will have a considerable effect on the extent of the losses.

The most common used ashing vessels are made of silica, porcelain, or platinum. Vitreous silica is a glass consisting almost entirely of  $\text{SiO}_2$ , with some Na, Al, Fe, Mg, and Ti oxide impurities, whereas the glaze on porcelain ware is a more complex material containing Al, K, Ca, and Na oxides (up to 30%) in addition to silica. For both vitreous silica and porcelain, the obvious reaction is between the oxide of the analyte and the ashing vessel to produce a complex silicate, resulting in a loss. Studies with radio-tracers have shown that retention of metals by reaction vessels made of vitreous silica may be very significant during dry ashing. This type of reaction clearly occurs but is dependent on many factors. Some oxides react much more readily than others and, even if silicates are formed, some will be stable to subsequent acid attack while others will readily be decomposed and so cannot be considered to cause losses. These reactions will, of course, be exacerbated if the ashing vessel is made of silica or porcelain, exhibits a marked weakening of the silicate structure, or a surface worn by extensive use.

Because the extent of such reactions remains unknown, the alternative practice of using essentially inert platinum crucibles is much more reliable. This metal is virtually unaffected by any of the usual acids, including hydrofluoric, but cannot be used for aqua regia digestion procedures. Of course, the initial cost for platinum is significantly higher than for other types of ashing vessel, but its lifetime is practically unlimited.

## Ashing Aids

In its initial form, a dry ashing procedure cannot be considered appropriate for preparation of samples to be used for the determination of As and Se. However, many of the reported ashing methods describe the addition of some extra inorganic compounds to the sample to improve the efficiency of the procedure. These added materials are generally called ashing aids, and they serve one or both of two purposes, i.e.,

to facilitate the decomposition of the organic matter, or to improve the recovery of the element to be determined.

The most common aid, used to purely hasten the oxidation of organic material, is nitric acid. It is generally added toward the end of the ashing process to decompose small amounts of remaining carbonaceous material. Since the ash from most biological materials contains up to several tens of percent carbonates, nitrates are formed *in situ* after the addition of nitric acid. Additional ashing is then, in fact, melting with nitrates and should help to remove the most resistant degradation products present in the organic matrix. This step, leading to the production of a clean ash, has to be performed with care because when appreciable amounts of organic material are still present, it can cause the ignition of the residue when it is returned to the furnace, resulting in a possible loss of material.

Some substances serve as auxiliary oxidants as well as serving other purposes. These are commonly the nitrates of light metals such as magnesium, calcium, or aluminum, which decompose on heating to yield oxides of nitrogen. These auxiliary oxidants also fulfill the important function of being inactive diluents in the process. As the organic matter in a sample is progressively decomposed, the analytes are brought into closer contact with the material of the vessel and other constituents of the residue. If a reaction with them is feasible, then the increased proximity will increase the chance of its occurrence. Under these circumstances, dilution of the ash with an inert material, such as magnesium oxide, should greatly reduce the possibility of undesirable solid-state reactions, resulting in improvement of recoveries. The well-known utilization of relatively unstable magnesium nitrate as an ashing aid likely offers both the advantage of more rapid oxidation and of decreased retention losses.

These oxidative-dilution agents improve recoveries without entering into any reaction with the sample itself. Another group of ashing aids achieves the same end by altering the chemical nature of some of the constituents. The best example of this is the use of sulfuric acid to convert volatile chlorides to nonvolatile sulfates; this may prevent losses of Cd, Pb, or Cu up to  $\sim 750^{\circ}\text{C}$ .

Arsenic and selenium determinations can, in some cases and under particular conditions, also benefit from the advantages offered by a dry ashing procedure. The addition of ashing aids – generally MgO and/or  $\text{MgNO}_3$  – can give rise to less volatile As or Se compounds during the ashing procedure. The successful use of ashing aids is, of

course, strongly dependent on the initial form of the analyte.

In any case, utilization of ashing aids is a particularly delicate step because some successful examples cannot lead to generalizations: for routine use, the procedure necessitates a serious and time-consuming validation for each type of sample analyzed. In addition, the utilization of ashing aids significantly increases the total dissolved solids content of solutions and enhances the dangers of contamination, limiting strongly the use of this approach for trace element analysis.

## Oxygen Flask Combustion

### Introduction

Oxidation of organic substances by means of combustion in an oxygen-rich atmosphere is one of the most popular techniques for sample decomposition for elemental analysis. During combustion, heteroatoms in the organic substances are converted into inorganic forms that can be readily analyzed subsequently using various techniques employed in elemental analysis. When a sample is oxidized in a closed system, loss of volatile compounds during combustion and contamination from the laboratory atmosphere can be avoided. Thus, a closed flask is normally used during combustion to reduce contamination.

The oxygen flask is the most simple closed combustion apparatus which is made of Pyrex (borosilicate) glass, it facilitates rapid elemental analysis in laboratories.

The oxygen flask method (also known as the Schöniger flask combustion method) has been designed for combustion of organic samples in the milligram region (normally less than 20 mg) prior to elemental analysis. The sample is wrapped in a piece of paper, placed in a platinum basket, and burned in a sealed flask filled with pure oxygen under 1–2 atm pressure. The flask is fitted with a ground glass

stopper and inverted. The absorption solution provides a liquid seal. Thereafter the sample is ignited either through an electrical discharge or infrared irradiation. This method is commonly used for elemental analysis of biological and organic materials. Compared with other methods for mineralization of organic matrices, the oxygen flask method is rapid, simple, and economic and uses glass apparatus readily available in most analytical laboratories.

The present article will cover the development of the methodology since 1995, with its focus on the direction taken by development, analytical techniques coupled with oxygen flask combustion, new areas of application, and future areas of development.

### Basic Procedures

The basic procedure using the oxygen flask method for elemental analysis is shown in the flowchart given in **Figure 1**. The procedures can be divided into three types. The first type includes wet chemical procedures used for sample preparation before combustion and after combustion treatments. The second type consists of hyphenated analytical techniques developed for elemental analysis using oxygen flask combustion. The third and the most important type is the oxidation of organic samples carried out inside a sealed oxygen flask under pure oxygen. A high recovery and a good absorption of oxidized products are needed in this step to ensure complete conversion of analytes into detectable inorganic forms. The basic oxygen flask combustion has not changed much since

**Figure 1** Flowchart showing the basic procedures using the oxygen flask method for elemental analysis. IC, ion chromatography; ICP-AES, inductively coupled plasma-atomic emission spectrometry; ISE, ion selective electrodes.

1995, and there has been a major change only in sample preparation before combustion and in post-combustion treatments; new hyphenated analytical techniques have also been developed for elemental analysis using oxygen flask combustion. These developments will be discussed in the following sections.

## **Sample Preparation Procedures**

The sample preparation procedure is mainly used for two purposes. The first purpose is distinguish different forms either for nutritional purposes, such as the determination of free or bounded iodine in food samples, or for differential toxicity so as to assess different fluorotensides in ecotoxicological experiments by their differential adsorption at an activated carbon surface.

The second purpose is to extend the scope of the radiochemical neutron activation analysis (RNAA) method. Preirradiation of inorganic samples to induce fission products prior to oxygen flask ignition and solvent extraction can be used to distinguish ionic and nonionic form. The use of double irradiation in RNAA allows the determination of nuclides with short, medium, and long lives in a single experiment. This enables simultaneous determination of  $^{127}\text{I}$ ,  $^{128}\text{I}$ ,  $^{235}\text{U}$ ,  $^{133}\text{I}$ , and  $^{203}\text{Hg}$ .

## **Postcombustion Treatment Procedures**

Procedures that have undergone significant development in the period are the various postcombustion treatment procedures developed with an aim to improving the absorption of gaseous analytes, to facilitate chemical conversion into a suitable form for detection, to concentrate the analytes to detectable levels, and enable the use of a selected analytical method for quantitation of analytes in total or free elemental form. Two major procedures have been developed, optimization of the composition of the absorption solutions and the development of techniques to concentrate analytes prior to their determination using an analytical technique for elemental analysis.

### **Optimization of Absorption Solutions**

The selection of a suitable absorption solution with high recovery of analytes is a critical area of elemental analysis using the oxygen flask method. The addition of  $\text{H}_2\text{O}_2$  to enhance the absorption of sulfur compounds is dealt with in several papers. To assist absorption of sulfur dioxide, two absorption solution systems have been developed. The first system uses 3% pure  $\text{H}_2\text{O}_2$  and the second absorption solution is

made up by mixing 100  $\mu\text{l}$  of 1%  $\text{H}_2\text{O}_2$  with 20 ml of 2  $\text{mmol l}^{-1}$  NaOH prior to making up to 100 ml by deionized (DI) water. To enhance bromine and iodine adsorption, 20 ml of 2  $\text{mmol l}^{-1}$  NaOH and 100  $\mu\text{l}$  of 5%  $\text{NH}_2\text{NH}_2$  are mixed prior to making up to 100 ml absorption solution with deionized water. An alkaline solution of 1,3-dibromo-5,5-dimethylhydantoin (DBH) has been used to improve iodine determination. In addition to enhancing analyte absorption, other reagents needed in the detection method are added to the absorption solution for formation of a colored complex or compounds required in subsequent titration and spectrophotometry. Various new reagents and complexes have been synthesized to enable the use of a specific analytical technique.

### **Preconcentration of Analyte**

There are two methods that can be used to concentrate analytes prior to analysis using the chosen method. The first method is conversion of different ionic products into a single form to increase the recovery. One example is the postcombustion hydrolysis used for phosphorus determination. The procedure consists of boiling the oxidation products in dilute  $\text{H}_2\text{SO}_4$  at 200°C for 20 min to ensure complete conversion from various different forms of phosphorus anions such as  $\text{P}_2\text{O}_7^{4-}$  and  $\text{P}_3\text{O}_{10}^{5-}$  into orthophosphate ( $\text{PO}_4^{3-}$ ) before ion chromatography (IC) analysis to increase the recovery.

The second method uses preconcentration to increase the analyte concentration in the absorption solution to detectable levels prior to analysis. One example is the use of solid-phase extraction with an anion exchange column as a pretreatment technique to remove interference from the sample matrix and to enhance the detection sensitivity prior to determination of the concentrated iodide anion through reversed phase high-performance liquid chromatography (HPLC) using an ultraviolet (UV) detector. The results show more than 90% recovery and good reproducibility for the determination of trace iodine in iodine-enriched eggs.

A summary of the new procedures reported since 1995 using the oxygen flask method for elemental analysis is given in Table 1 with a focus on the areas of development in the basic procedure. It is obvious from the table that the amount of work on multi-elemental analysis has increased, though techniques for single element determination are still the major thrust. Details of the development of the oxygen flask combustion method for single element and multi-element determination will be given in the next section.

**Table 1** Summary of new procedures developed using the oxygen flask method for elemental analysis since 1995

Analyte	Sample	Sample preparation and postcombustion treatment	Analytical methods	Remarks
I	Organic compounds	A new reagent, DBH, has been used to improve the determination of iodine due to the favorable removal of excess of DBH 5-sulfosalicyclic acid prior to determination	Volumetric titration	
	Food	Alkaline absorption solution	IC	
	Eggs	Use of solid-phase extraction and anion exchange column for Preconcentration of I	HPLC	Total I
	Food colors	Mix 20 ml of 2 mmol l <sup>-1</sup> NaOH with 100 µl of 5% NH <sub>2</sub> NH <sub>2</sub> and make up to 100 ml by DI water as absorption solution	Direct injection into IC for free I <sup>-</sup> and after oxygen flask combustion for total I	Use of ceramic carbon column for total I <sup>-</sup> and free I <sup>-</sup>
F	<i>p</i> -Fluorobenzoic acid and dexamethasone	New metallofluorescent reagent (CNDA) made to assist fluorophotometric detection	Fluorophotometric titration	Total F
	Organic compounds	Titration with AlCl <sub>3</sub> solution	Potentiometric titration	Total F
	Organic pharmaceutical compounds	Fluoride-ISE compared with volumetric titration, with excess Ce(III) back-titrated with ethylenediaminetetraacetic acid (EDTA). Addition of TISAB prior to fluoride-ISE determination	Fluoride-ISE	Total F with good agreement between two methods
	Hair	Addition of TISAB	Fluoride-ISE	Determine total F for fluorosis of workers in polluted environment
	Sediment and plants	Adsorption of fluorotensides at active carbon, filtration, dry and oxygen flask combustion. Addition of TISAB prior to fluoride-ISE determination.	Fluoride-ISE	Determine total F for ecotoxicology experiments
S	Plant materials	H <sub>2</sub> O <sub>2</sub> as absorption solution	IC and ICP–AES	Total S
	Organic materials	Improved recovery using sealed tube (580°C for 20 min) and 3% H <sub>2</sub> O <sub>2</sub> absorption solution for samples of 1 mg or below	Spectrophotometric titration	Total S
Cl <sup>-</sup> , Br <sup>-</sup> , SO <sub>4</sub> <sup>2-</sup>	Colour additives	20 ml of 2 mmol l <sup>-1</sup> NaOH and 100 µl of 5% NH <sub>2</sub> NH <sub>2</sub> to make up to 100 ml for Br absorption 20 ml of 2 mmol l <sup>-1</sup> NaOH and 100 µl of 1% NaOH/H <sub>2</sub> O <sub>2</sub> to make up to 100 ml for S absorption	IC developed by mobile phase of 2 mmol l <sup>-1</sup> Na <sub>2</sub> CO <sub>3</sub> , 1 mmol l <sup>-1</sup> TEA in 5% acetonitrile	Ceramic carbon column

Continued

**Table 1** Continued

Analyte	Sample	Sample preparation and postcombustion treatment	Analytical methods	Remarks
F, Cl, Br, S	Organic compounds	Suppress background of NO <sub>x</sub> and CO <sub>2</sub> using standard organic compounds	IC	Microdetermination
P, Cl, Br, S	Organic compounds	Dilute aqueous H <sub>2</sub> O <sub>2</sub> as absorption solution use of postcombustion hydrolysis to increase recovery within 0.3% of theoretical values	Boil in dilute H <sub>2</sub> SO <sub>4</sub> at 200°C for 20 min to ensure conversion from P <sub>2</sub> O <sub>7</sub> <sup>4-</sup> and P <sub>3</sub> O <sub>10</sub> <sup>5-</sup> to PO <sub>4</sub> <sup>3-</sup> before IC separation	Microdetermination
F <sup>-</sup> , Cl <sup>-</sup> , NO <sub>2</sub> <sup>-</sup> , Br <sup>-</sup> , NO <sub>3</sub> <sup>-</sup> , SO <sub>4</sub> <sup>2-</sup> , HPO <sub>4</sub> <sup>2-</sup> , I <sup>-</sup>	Organic compounds	Alkaline absorption solution	IC developed by mobile phase of 4 mmol l <sup>-1</sup> Na <sub>2</sub> CO <sub>3</sub> , 1 mmol l <sup>-1</sup> TEA in 7.5% acetonitrile	Ceramic carbon column coated with DBS
F <sup>-</sup> , Cl <sup>-</sup> , NO <sub>2</sub> <sup>-</sup> , Br <sup>-</sup> , NO <sub>3</sub> <sup>-</sup> , HPO <sub>4</sub> <sup>2-</sup> , SeO <sub>3</sub> <sup>2-</sup> , SeO <sub>4</sub> <sup>2-</sup> , SO <sub>4</sub> <sup>2-</sup>	Organic compounds	Water as absorption solution	Suppressed IC with anion micromembrane suppressor and conductivity detector	Shodex IC IF-424 anion exchange column
Se	Blood plasma and hair	Formation of a Se ternary inclusion compound at β-CD cavity with anionic surfactant SDS leads to a 10-fold enhancement in fluorescence	Ternary inclusion compound–fluorescent spectrophotometry	Low correlation between hair Se and Plasma Se levels
W	Organic compounds	Titration with Pb(NO <sub>3</sub> ) <sub>2</sub> by Pb ISE after removal of CO <sub>2</sub> and adjusting buffer pH	Potentiometric titration	Recoveries of W from 99.74–100%
Ce(III), Th(IV), and U(VI)	Chelates	Ce(III) determined as yellow formaldoxime complex at 400 nm; Th(IV) determined as arsenate(III) complex at 660 nm; U(VI) determined as complex at 555 nm	Volumetric titration and spectrophotometric titration	Microdetermination
<sup>127</sup> I, <sup>128</sup> I, <sup>235</sup> U <sup>133</sup> I and <sup>203</sup> Hg	Sediments and soil	Preirradiation to induce fission products prior to ignition of oxygen flask and solvent extraction	RNAA	Double irradiation enables analysis of short- medium-, and long-life nuclides

CNDA, 3-carboxy-2-naophthylamine-*N,N*-diacetic acid; DBS, dodecylbenzenesulfonic acid; IC, ion chromatography; ICP-AES, inductively coupled plasma-atomic emission spectrometry; ISE, ion selective electrodes; TEA, tetrabutylammonium hydroxide.

## Analytical Techniques for Elemental Analysis

The various analytical techniques used for elemental analysis after oxygen flask combustion can be divided into two different types, those targeting a single element and those focusing on multielement analysis. In general, analytical techniques based on titration, those using ion-selective electrodes (ISEs), spectrophotometry, and spectrofluorimetry are used in single element determination, whereas separation methods based on IC, and HPLC are used for multielement determination after oxygen flask combustion.

### Single Element Determination

The analytical techniques used for single element analysis can be divided into three groups. The first group consists of titration techniques using various means to detect the end point of titration, such as volumetric titration, fluorophotometric titration, potentiometric titration, and spectrophotometric titration. The second group includes direct detection techniques such as direct ternary inclusion compound fluorescent spectrophotometry and the use of ISEs. The third group is that of separation methods such as IC and HPLC, which are used in complicated sample matrices to reduce the sample matrix interference.

### Titration and Direct Detection

New procedures for titration have been developed based on the synthesis or availability of new reagents or complexes that enable sensitive and selective detection of a given analyte. For example, a new metallofluorescent reagent, 3-carboxy-2-naphthoylamine-*N,N*-diacetic acid (CNDA), has been synthesized for fluorophotometry and as a metallofluorescent indicator for chelatometric titration, and a new reagent, DBH, has been developed to improve the determination of iodine as the removal of excess DBH 5-sulfosalicylic acid prior to determination is more suitable than that of the formic acid currently in use. For potentiometric microdetermination of tungsten, a hydrolysis step is taken in boiling the solution for 6–7 min after combustion to ensure complete dissolution of the  $WO_3$  formed during combustion. Procedures have been developed for the removal of  $CO_2$  and the adjustment of buffer pH prior to the use of a Pb(II) ISE as indicator electrode for potentiometric titration of W(VI) using  $10 \text{ mmol l}^{-1}$   $Pb(NO_3)_2$  solution to reduce sample matrix interference and to produce results consistent to standard methods.

For direct detection, a fluorometry based on a new ternary inclusion compound has been developed to enhance the detection sensitivity for Se

determination. The conventional fluorometric method for Se determination uses a fluorescent compound (2,3-diaminonaphthalene (DAN)–Se) formed between Se and DAN. The formation of a ternary inclusion compound in the cavity of  $\beta$ -cyclodextrin ( $\beta$ -CD) by reacting anionic surfactant sodium dodecylsulfate (SDS) with Se has been shown to produce a 10-fold enhancement in fluorescence and a significant decrease in the detection limit of the method employed. Various procedures using the fluoride ISE (fluoride-ISE) have been developed for direct and indirect determination of fluoride after oxygen flask combustion. Total ionic strength adjusting buffers (TISABs) are added to the absorption solution after combustion prior to the use of fluoride-ISE to produce a uniform ionic activity and reduce sample matrix interference.

### Separation Method for Complex Samples

Procedures based on separation techniques such as HPLC and IC have been developed for single element analysis for the following two reasons. The first reason is to remove interferents in complicated sample matrices that can give rise to incorrect results, in particular for trace analysis in samples with a high organic content, such as the determination of total iodine in egg products. The second reason is to differentiate the total and free forms of a specific element, such as the determination of the free iodide ion and bounded iodine in food additives. The free iodide ion is determined by direct sample injection into the IC column, whereas the total iodine content is determined after oxygen flask combustion. Thus, both the free and bounded forms of iodine in food samples can be determined.

### Multielement Determination

The following three analytical techniques have been developed for multielement determination after oxygen flask combustion: inductively coupled plasma (ICP)–atomic emission spectrometry (AES), IC, and RNAA. ICP–AES is mainly used for trace metal analysis and RNAA for multiple isotope determination in inorganic materials. From the summary of new procedures developed since 1995 using the oxygen flask method for elemental analysis listed in Table 1, it is clear that IC is the major analytical technique behind the recent development of multielement determination for oxygen flask combustion, in particular for organic samples.

### Ion Chromatography

Suppressed IC was initially developed using an anion micromembrane suppressor and a conductivity

detector for multiple trace anion determination that could be used for multielement determination after oxygen flask combustion. However, the high cost of the equipment has restricted its use even in well-funded laboratories and the need for a second suppressor column has dictated the type of eluent used and limited the separation ability of the method. A strong alkaline mobile phase is used for separation, and this leads to the requirement of a special column such as the Shodex IC IF-424 anion exchange column for separation of the group of anions of interest in elemental analysis.

The recent advancement of nonsuppressed IC provides an attractive alternative method as ordinary HPLC equipment with UV detectors and reverse phase columns can be used for separation of the group of anions of interest in elemental analysis. Due to the strong competition among HPLC manufacturers in using their well established technology for an increasing market, the cost of HPLC equipment with UV detectors has come down considerably and within the budget for most laboratories. In addition, a weak acid mobile phase (typically 2 mmol l<sup>-1</sup> potassium hydrogen phthalate with eluent pH adjusted to 5.0) is used for separation using an ordinary reverse phase HPLC column (for example, a Hamilton PRP-X100 column). Thus, subsequent analysis of the anionic products generated from oxygen flask combustion can be performed in many laboratories equipped with HPLC apparatus. This has led to the popularity of using IC for multielement analysis as reported in the literature.

However, there are two major problems in the development of IC procedures for multielement determination. The first problem is the sloping of the baseline for samples with high organic contents such as wax, transformer oil, and lubricating oil. The second problem is the mutual interference of adjacent pairs of anions in an ion chromatogram with a large difference in concentration. The baseline stability problem is attributed to the high level of carbonates in solution as the result of absorption of carbon dioxide generated during combustion of samples with a high organic content. The effect of carbonate on the separation of common anions is shown in **Figure 2**. Carbonate is eluted just behind the injection peak, and the two peaks are so close that they are coeluted as a single peak in the ion chromatogram. Poor retention of CO<sub>3</sub><sup>2-</sup> is due to the formation of HCO<sub>3</sub><sup>-</sup>/H<sub>2</sub>CO<sub>3</sub> at an eluent pH of 5.0, a weak acid with little interaction with the analytical column. For CO<sub>3</sub><sup>2-</sup> concentrations greater than 50 µg ml<sup>-1</sup>, broadening and tailing of the injection peak are observed. Thus, early eluted monovalent anions such as F<sup>-</sup>, H<sub>2</sub>PO<sub>4</sub><sup>-</sup>, and Cl<sup>-</sup> could be

**Figure 2** The effect of carbonate on the separation of common anions. (A) anion standards with 60 µg ml<sup>-1</sup> CO<sub>3</sub><sup>2-</sup>; (B) without CO<sub>3</sub><sup>2-</sup>. Conditions: eluent = 2 mol l<sup>-1</sup> KHP, pH 5.0; detection at 272 nm; flow rate = 1.5 ml min<sup>-1</sup>; sample volume = 100 µl. Peaks: (a) 3 µg ml<sup>-1</sup> F<sup>-</sup>; (b) 5 µg ml<sup>-1</sup> H<sub>2</sub>PO<sub>4</sub><sup>-</sup>; (c) 4 µg ml<sup>-1</sup> Cl<sup>-</sup>; (d) 2 µg ml<sup>-1</sup> Br<sup>-</sup>; (e) 5 µg ml<sup>-1</sup> NO<sub>3</sub><sup>-</sup>; (f) 10 µg ml<sup>-1</sup> SO<sub>4</sub><sup>2-</sup>. (Reprinted with permission from Fung YS and Dao KL (1996) Elemental analysis of chemical wastes by oxygen bomb combustion-ion chromatography. *Analytica Chimica Acta* 334: 51–56; © Elsevier.)

masked by the injection peak. Although diluting the CO<sub>3</sub><sup>2-</sup> solution could reduce the interference, it also lowers the sensitivity of the method to detecting other low-level heteroatoms.

The stability of the baseline can be improved as shown in **Figure 3** by passing the absorption solution through a cation exchange resin column to convert it into H<sub>2</sub>CO<sub>3</sub> prior to removing CO<sub>2</sub> by heating the solution. Thus, it enables the detection of low levels of F<sup>-</sup> and Cl<sup>-</sup> in real samples, as shown by the chromatogram of a motor oil sample as given in **Figure 4**. By spiking anion standard solutions after the combustion of kerosene prior to ion exchange treatment, over 96% recoveries are obtained for F<sup>-</sup>, H<sub>2</sub>PO<sub>4</sub><sup>-</sup>, Cl<sup>-</sup>, Br<sup>-</sup>, and SO<sub>4</sub><sup>2-</sup> with a relative standard deviation (RSD) less than 6%, linear ranges up to three orders of magnitudes, repeatability of less than 2%, and detection limits at sub µg ml<sup>-1</sup> levels for all analyte anions.

The mutual interference between closely eluted analyte peaks in an ion chromatogram are shown in **Table 2**. Three critical adjacent ion pairs have been identified as follows: H<sub>2</sub>PO<sub>4</sub><sup>-</sup> on F<sup>-</sup>, F<sup>-</sup> on H<sub>2</sub>PO<sub>4</sub><sup>-</sup>, and NO<sub>3</sub><sup>-</sup> on Br<sup>-</sup>. As the retention times of F<sup>-</sup> and H<sub>2</sub>PO<sub>4</sub><sup>-</sup> are 2.4 and 2.8 min, respectively, the peak resolution between F<sup>-</sup> and H<sub>2</sub>PO<sub>4</sub><sup>-</sup> decreases gradually as their concentration are increased. For the determination of 1 µg ml<sup>-1</sup> F<sup>-</sup>, the error is less than 5% for a H<sub>2</sub>PO<sub>4</sub><sup>-</sup> concentration up to 25 µg ml<sup>-1</sup>.

**Table 2** The interference between closely eluted pairs of analyte peaks on ion chromatograms

Anion 1	Concentration ( $\mu\text{g ml}^{-1}$ )	Anion 2	Concentration ( $\mu\text{g ml}^{-1}$ )	Error in measuring anion 1 in presence of anion 2 (%)
Fluoride	1	Phosphate	5	0
	1		10	–1
	1		15	–1.8
	1		20	–2.8
	1		25	–4.8
	1		30	–6.3
Phosphate	5	Fluoride	0.5	0.1
	5		1	0.2
	5		2	–1.1
	5		3	–2.1
	5		4	–5
	5		5	–11
Bromine	2	Nitrate	5	–0.2
	2		10	–0.8
	2		15	–1.3
	2		20	–4.1
	2		25	–5.5
	2		30	–8.6

However, due to the higher peak height response of  $\text{F}^-$ , the determination of  $5 \mu\text{g ml}^{-1} \text{H}_2\text{PO}_4^-$  leads to a more than 10% error for an  $\text{F}^-$  concentration greater than  $5 \mu\text{g ml}^{-1}$ . For  $\text{Br}^-$  and  $\text{NO}_3^-$ , only the interference of  $\text{NO}_3^-$  on  $\text{Br}^-$  is considered because elemental analysis of nitrogen is not possible due to the variable oxidation of atmospheric nitrogen during combustion. A less than 5.5% error has been obtained for measuring  $2 \mu\text{g ml}^{-1} \text{Br}^-$  in the presence of  $\text{NO}_3^-$  up to  $25 \mu\text{g ml}^{-1}$ . A suitable dilution

can be carried out to reduce the nitrate interference for samples with a low  $\text{Br}^-$  content.

To compensate for the interfering effect of  $\text{CO}_3^{2-}$  and  $\text{NO}_3^-$  on the determination of  $\text{F}^-$ ,  $\text{Cl}^-$ ,  $\text{Br}^-$ , and  $\text{S}^-$ , calibration curves based on different ratios of atomic compositions using organic standards with specified ratios of heteroatoms have been constructed. An automatic selecting program has been devised to select the most suitable calibration curve for a given sample. Highly accurate results have been

obtained, and the overall performance of the procedure is highly efficient and practical for the determination of a large number of samples with multiple elements.

### Metals, Isotopes, and Others

The following analytical techniques have been developed for multielement determination: ICP-AES, RNAA, and the chelating titration method. ICP-AES has been used for total sulfur determination. For multiple trace metal analysis, the trend is toward direct determination without combustion, in particular for organic compounds. For RNAA, a procedure has been developed to combine the determination of short-life nuclides with medium- and long-life nuclides by making a medium or long irradiation prior to short irradiation and radiochemical processing. Thus, an RNAA procedure has been developed using oxygen flask ignition of the irradiated samples for the determination of  $^{127}\text{I}$ ,  $^{128}\text{I}$ ,  $^{235}\text{U}$ ,  $^{133}\text{I}$ , and  $^{203}\text{Hg}$  in biological and environmental samples. Spectrophotometric procedures have been developed for determination of the chelates of Ce(III) at 400 nm, Th(IV) at 660 nm, and U(VI) at 555 nm.

### Applications

Applications of the oxygen flask method range from traditional elemental analysis of organic compounds to samples with more complicated matrixes such as food products, plant material (citrus leaf, canola seed, corn leaf, pine needle, red clover shoot, wheat flour, and orchard grass), organic pharmaceutical compounds, hair, sediment, and soil samples. For practical sample analysis, method validation is important. Two approaches have been adopted to check the validation of the method developed. First, the recovery of spiked standards is assessed normally, with results showing greater than 90% recoveries for all analytes investigated. Second, a parallel method comparison is performed to check the consistency of results, in particular on real samples with no primary standards available. Results of comparisons of various analytical methods employed for method validation are given in Table 3.

The results of the recently developed commercial automated oxidation equipment have been compared with those obtained from the traditional oxygen flask method for various plant materials. Out of the six methods compared (dry ashing/ICP-AES, oxygen flask/ICP-AES, oxygen flask/IC, automated combustion, microwave ( $\text{HNO}_3/\text{HClO}_4$ )/ICP-AES, microwave ( $\text{HNO}_3/\text{H}_2\text{O}_2/\text{HCl}$ )/ICP-AES), the oxygen flask/IC and oxygen flask/ICP-AES are found to give similar total sulfur content for all six plant tissues types

studied, indicating complete oxidation of the plant sulfur to sulfate. The low results obtained by other methods are attributed to incomplete destruction and sulfur volatilization during combustion.

Parallel method comparisons are used to establish the validity of a new method developed for five organic pharmaceutical compounds, food colors, and color additives. The standard methods such as the Japanese Standard Food Additives and Japanese Standard of Cosmetic Ingredients method, based on volumetric and gravimetric titration, have been used to establish new methods developed for the determination of I, Cl, Br, and  $\text{SO}_4^{2-}$  in food colors. The results obtained indicate good agreement in both accuracy and precision for procedures based on the oxygen flask method as compared with the standard methods. In addition to anion elemental analysis, method validation has also been carried out for metal analysis such as that of Ce(III), Th(IV), and U(VI), with the results showing acceptable limits of variation.

Analyzing elements with and without the use of the oxygen flask, the free and bounded forms of a given element can be determined. This scheme has been adopted in assessing free and bounded iodine for nutritional assessment. Different forms can also be differentiated by their differential adsorption during sample preparation prior to oxygen flask combustion. This scheme has found an application in assessing the risk for fluorosis of workers in polluted environments and in ecotoxicology studies.

Despite the recent development of commercial automated oxygen combustion equipment, the oxygen flask combustion method remains a method for choice for elemental analysis in many laboratories due to its simple, rapid, and economic procedure using readily available apparatus. From the record of the past 5 years, three directions of development of the oxygen flask method can be seen. First, it shows a trend toward microdetermination, in particular for samples of less than 1 mg. Second, new procedures have been developed for multielement determination after oxygen flask combustion, mostly based on IC separation of the anions produced. Third, extensive validation of the procedure developed has been carried out for real sample analysis with a parallel method comparison with two to six different procedures.

The three directions will certainly be continued in future. For microdetermination and multielement analysis, new procedures based on the recently developed capillary electrophoresis are expected to come, in particular for cases with limited sample sizes. The applicability to real sample analysis is expected to grow, together with work on validation of the methodology developed. A survey has been

**Table 3** Comparison of analytical methods for elemental analysis after combustion

Analyte	Sample	Methods compared	Summary of results	Remarks
S	Plant materials (citrus leaf, canola seed, corn leaf, pine needle, red clover shoot, wheat flour)	A (dry ashing/ICP–AES) B (oxygen flask/ICP–AES) C (oxygen flask/IC) D (automated combustion <sup>b</sup> ) E (microwave (HNO <sub>3</sub> /HClO <sub>4</sub> )/ICP–AES) F (microwave (HNO <sub>3</sub> /H <sub>2</sub> O <sub>2</sub> /HCl)/ICP–AES)	Average results for two daily batches of three subsamples from each of six tissues ( $n=36$ ) indicate $D = F > B = C = A > E$ B and C gave similar S values for all tissue types, indicating complete oxidation of plant S to sulfate	Total S

conducted using the oxygen flask method for measuring Se in blood plasma and in hair for toxic metal risk assessment. Given the extensive work done on method validation for elemental analysis of various plant materials using the oxygen flask method, this method is expected to provide a routine method for screening food products and plant material in the coming years as a validated method using a cheap and rapid procedure with readily available glass apparatus is the necessity for large-scale screening work.

### Introduction

Wet digestion methods for elemental analysis involve the chemical degradation of sample matrices in solution, usually with a combination of acids to increase solubility. The various acid and flux treatments are carried out at high temperatures in specially designed vessels that help to minimize contamination of the sample with substances in the air, the local environment, and from the vessel walls. Losses from the sample may occur due to adsorption onto the vessel walls, volatilization, and coextraction, but these can be reduced by procedural modifications. The use of closed systems, where the digestion reaction is completely isolated from the surroundings, may help to reduce both contamination and sample loss.

### The Nature of the Sample Matrix

Many techniques employed for elemental analysis require the conversion of the sample matrix into a solution form. The selection of an appropriate treatment for sample dissolution depends on the nature of the sample, and different approaches are required for predominantly inorganic and predominantly organic matrices. Geological, geochemical, and soil samples generally contain silicate, metal oxides, carbonates, and, in many cases, organic matter. Such samples must be dried and ground to a fine powder to

facilitate dissolution. Minerals and coal often have a nonuniform distribution of elements, while fly ash is very fine and is composed of metal silicates and oxides. Both these types of sample are difficult to solubilize. Similarly, alloys can be difficult to dissolve because of the strong bonds between metal atoms and their brittle nature. Solid and crystalline samples may possess interstitial water and water of crystallization, so thorough drying of samples is necessary before and after grinding.

Biological samples must be processed with great care, since the dissolution and total decomposition of all organic matter is required for the release of trace elements. However, the use of oxidizing acids to decompose organic matter can produce violent reactions and the alternative procedure of dry ashing may be more suitable in some cases. Environmental and water samples often contain mixtures of organic and inorganic substances, so dissolution techniques need to be modified to take this composition into account. In particular, water samples may contain dissolved and suspended solids, colloids, and microorganisms. Elements embedded in such samples may be present both in dissolved and solid forms. The nature of the sample matrix must be given special attention during wet digestion.

### Extraction of the Analyte

Solid samples generally contain some adsorbed and/or absorbed water. In the case of inorganic materials, drying is carried out in an oven at 105–110°C for a few hours, although lower temperatures need to be used if the sample contains volatile components. On the other hand, higher temperatures may be required to remove water trapped within crystalline matrices.

### Introduction

Wet digestion methods for elemental analysis involve the chemical degradation of sample matrices in solution, usually with a combination of acids to increase solubility. The various acid and flux treatments are carried out at high temperatures in specially designed vessels that help to minimize contamination of the sample with substances in the air, the local environment, and from the vessel walls. Losses from the sample may occur due to adsorption onto the vessel walls, volatilization, and coextraction, but these can be reduced by procedural modifications. The use of closed systems, where the digestion reaction is completely isolated from the surroundings, may help to reduce both contamination and sample loss.

### The Nature of the Sample Matrix

Many techniques employed for elemental analysis require the conversion of the sample matrix into a solution form. The selection of an appropriate treatment for sample dissolution depends on the nature of the sample, and different approaches are required for predominantly inorganic and predominantly organic matrices. Geological, geochemical, and soil samples generally contain silicate, metal oxides, carbonates, and, in many cases, organic matter. Such samples must be dried and ground to a fine powder to

facilitate dissolution. Minerals and coal often have a nonuniform distribution of elements, while fly ash is very fine and is composed of metal silicates and oxides. Both these types of sample are difficult to solubilize. Similarly, alloys can be difficult to dissolve because of the strong bonds between metal atoms and their brittle nature. Solid and crystalline samples may possess interstitial water and water of crystallization, so thorough drying of samples is necessary before and after grinding.

Biological samples must be processed with great care, since the dissolution and total decomposition of all organic matter is required for the release of trace elements. However, the use of oxidizing acids to decompose organic matter can produce violent reactions and the alternative procedure of dry ashing may be more suitable in some cases. Environmental and water samples often contain mixtures of organic and inorganic substances, so dissolution techniques need to be modified to take this composition into account. In particular, water samples may contain dissolved and suspended solids, colloids, and microorganisms. Elements embedded in such samples may be present both in dissolved and solid forms. The nature of the sample matrix must be given special attention during wet digestion.

### Extraction of the Analyte

Solid samples generally contain some adsorbed and/or absorbed water. In the case of inorganic materials, drying is carried out in an oven at 105–110°C for a few hours, although lower temperatures need to be used if the sample contains volatile components. On the other hand, higher temperatures may be required to remove water trapped within crystalline matrices.

Frequently, the sample is not soluble in water and must be treated with acids or mixtures of acids to facilitate solubilization. The type of acid treatment must be given careful consideration, since particular acids may or may not oxidize the sample, and may be incompatible with certain elements. For example, sulfuric acid cannot be used to dissolve samples containing barium, while hydrochloric acid cannot be used to dissolve silver or samples containing lead and lead compounds. The choice of acid is also restricted by sample volatilization, e.g., hydrochloric acid should be avoided in samples containing arsenic since this is more volatile as a trichloride.

Naturally occurring inorganic materials, such as ores, must be given special treatments to facilitate solubilization. The two most common methods employed in dissolving samples are treatments with hydrochloric, hydrofluoric, nitric, sulfuric, or perfluoric acids (or various combinations thereof) and fusion with an acidic or basic flux followed by treatment with water or an acid. Organic materials are usually decomposed by wet digestion with a boiling oxidizing acid or acid mixture, ultimately producing carbon dioxide, water, and other volatile compounds that are driven off to leave behind salts or acids of the inorganic constituents of the sample. Wet digestions may be performed in open beakers on hot plates, but Kjeldahl flasks or specially designed containment vessels give results that are more satisfactory.

### Wet Digestion with Single Acids

The solvent action of an acid depends on several factors:

1. The reduction of hydrogen ions by metals that are more active than hydrogen, for example:  

$$\text{Zn(s)} + 2\text{H}^+ \rightarrow \text{Zn}^{2+} + \text{H}_2\text{(g)}.$$
2. The combination of hydrogen ions with anions of a weak acid, for example:  $\text{CaCO}_3\text{(s)} + 2\text{H}^+ \rightarrow \text{Ca}^{2+} + \text{H}_2\text{O} + \text{CO}_2\text{(g)}.$
3. The oxidizing properties of the acid anion, for example:  $3\text{Cu(s)} + 2\text{NO}_3^- + 8\text{H}^+ \rightarrow 3\text{NO(g)} + 4\text{H}_2\text{O}.$
4. The tendency of the acid anion to form soluble complexes with the sample cation, for example:  

$$\text{Fe}^{3+} + \text{Cl}^- \rightarrow \text{FeCl}^{2+}.$$

Ideally, the chosen reagent should cause the complete dissolution of the sample. As a general guide it is useful to classify the more common acid treatments according to whether they oxidize the sample or not. The nonoxidizing acids include dilute hydrochloric, hydrofluoric, sulfuric, and perchloric acids, whereas the oxidizing acids include hot, concentrated nitric, sulfuric, and perchloric acids. Dissolution of metals

by nonoxidizing acids is a process of hydrogen replacement.

Hydrochloric acid will dissolve metals above the standard reduction potential of hydrogen, salts of weak acids, and many oxides. Dilute sulfuric and perchloric acids are useful for metals above the standard reduction potential of hydrogen. Hot, concentrated sulfuric acid will often dissolve metals below the standard reduction potential of hydrogen. The most potent oxidizing conditions are obtained using hot concentrated perchloric acid, which will dissolve all common metals. Concentrated hydrochloric acid is an excellent solvent for many metal oxides as well as those metals that are more easily oxidized than hydrogen. In addition, it is often a better solvent for oxides than the oxidizing acids.

Hot, concentrated nitric acid will dissolve all common metals with the exception of aluminum and chromium, which are passive to the reagent as a result of surface oxide formation. Hot nitric acid also readily oxidizes many organic substances. Hot, concentrated sulfuric acid can be used to decompose and dissolve many substances in part because of its high boiling point (340°C), and it is particularly useful for the dehydration and oxidation of organic samples. Most metals and alloys are also attacked by this hot acid.

Perchloric acid is a potent oxidizing agent that leads to the formation of highly soluble perchlorate salts. As with sulfuric acid, perchloric acid dehydrates and oxidizes organic samples very efficiently. It also attacks iron alloys and stainless steel, which are resistant to other mineral acids. Care is required when using perchloric acid because it is explosive in contact with certain organic compounds and easily oxidized inorganic materials. Special chemical hoods are recommended. Perchloric acid, as a 72–74% solution, boils at 203°C.

Hydrofluoric acid is a weak, nonoxidizing acid that is particularly useful for dissolving silicate samples since it removes the silicon quantitatively as volatile  $\text{SiF}_4$ . In many cases, hydrofluoric acid dissolution can be achieved by adding sodium fluoride to samples treated with hydrochloric acid.

### Wet Digestion with Acid Mixtures

Acids in combination are preferred for certain inorganic matrices and are generally more advantageous for the decomposition of organic compounds. Wet digestion procedures using acid mixtures can be divided into four types:

1. Total decomposition, usually with hydrofluoric acid and another mineral acid.
2. Strong attacks, for routine analysis but leaving a residue of certain minerals, particularly

silicates. Carried out with various mixtures of sulfuric, nitric, and perchloric acids.

3. Moderate attacks, using weaker acid mixtures.
4. Partial digestions (acid leaching).

Both (3) and (4) are typically employed for environmental analysis where complete dissolution is either not required or is undesirable and the goal is to determine the presence of certain trace elements.

For geochemical samples containing silicates, the matrix is decomposed by heating with hydrofluoric acid in combination with either nitric or perchloric acid, each of which has a higher boiling point than hydrofluoric acid. The presence of the second acid with a higher boiling point ensures that, once the hydrofluoric acid has been boiled off and the dry sample redissolved, sparingly soluble metal fluorides are converted to salts that are more soluble. As stated above, however, caution should be exercised with the use of perchloric acid if the sample has a significant organic component. Perchloric acid is also more expensive than nitric acid, and can introduce chloride ions as contaminants.

For organic samples, a widely used mixture is aqua regia (1:3 nitric acid–hydrochloric acid). The nitric acid acts as the oxidizing agent, while the hydrochloric acid provides the complexing properties. The addition of bromine or hydrogen peroxide can sometimes increase the solubilizing power of mineral acids. Wet digestion is generally carried out in open flasks, covered loosely to avoid atmospheric contamination. However, it is becoming increasingly common to use closed vessels, such as polytetrafluoroethylene (PTFE)-lined containers or ultrapure quartz vessels, especially for small samples.

A 1:4 mixture of sulfuric and nitric acids is also widely employed for organic samples. The nitric acid decomposes the bulk of the organic matter but does not reach a temperature sufficient to destroy the last traces. However, as the nitric acid boils off, the sulfuric acid is left behind. Dense  $\text{SO}_3$  fumes evolve and begin to reflux in the flask, making the solution very hot and allowing the hot sulfuric acid to decompose the remaining organic matter. Because of the fumes produced in this method, it must be carried out under a fume hood. More nitric acid may be added to prolong the digestion and eliminate any stubborn organic material.

A very efficient acid mixture is nitric, sulfuric, and perchloric acid in a volume ratio of  $\sim 3:1:1$ . For a typical 10 g sample of tissue or blood, 10 ml of this solution is sufficient for complete dissolution. The samples are heated until the nitric acid boils off and perchloric acid fumes begin to appear. Heating continues until the perchloric acid boils off and  $\text{SO}_3$

fumes appear. There is little danger of perchloric acid explosions as long as sufficient nitric acid is present to decompose the bulk of the organic matter, and as long as sulfuric acid remains after the perchloric acid has evaporated to prevent the sample becoming dry. Perchloric acid should never be added directly to an organic sample. A mixture of nitric and perchloric acid may also be used.

The availability of strong hydrogen peroxide solutions allows a combination of sulfuric acid and hydrogen peroxide to be used for the decomposition of organic matter. Hydrogen peroxide is a vigorous oxidizing agent and is particularly useful for the degradation of resistant plastics. There is little danger of explosion if sulfuric acid is present in excess. Most elements can be recovered quantitatively in this procedure, with the exceptions of ruthenium, osmium, germanium, arsenic, and selenium. In the case of germanium and arsenic, loss is attributable to volatilization of chlorides. Additionally, precipitated calcium sulfate may retain lead and silver if not solubilized. After decomposition, the sulfuric acid solution should be diluted and boiled gently for 10 min to destroy any remaining hydrogen peroxide.

The recovery of trace elements after wet digestion using the methods described above is compared in Tables 1 and 2.

Concentrated and fuming  $\text{HNO}_3$ .

500 ml flask used for 2 g cocoa sample.

Radioactive nuclides were used to determine recovery of 1–10 mg  $\text{kg}^{-1}$  level.

### Wet Digestion with Fluxes

Some materials are particularly resistant to acid digestion, e.g., certain rocks, mineral oxides, phosphates, and some iron alloys. For these samples, high-temperature fusion with an acidic or basic flux such as lithium metaborate ( $\text{LiBO}_3$ ) in the molten state can be used to render such materials soluble in water or dilute acid. Fusion decompositions are the most rigorous methods available and all silicate materials, including refractory substances like zircon and cassiterite, can be dissolved completely when fused with an appropriate flux. However, there are several disadvantages to this method including the introduction of additional salts into the final solution

**Table 2** Recovery of metals from various biomaterials after wet digestion

Sb	99	95	94	94	100

Ag, Co, Cr, Cu, Mn, Mo, Pb, V, Zn: 98–102% for all samples. Samples: 5 ml horse blood; 250 mg sugar beat leaves; 10 ml urine; 1.5 g animal tissue.

Digested for 1.5 h with 5 ml of a mixture of 98%  $\text{H}_2\text{SO}_4$ , 70%  $\text{HClO}_4$ , and 66%  $\text{HNO}_3$  in the volume ratio 1:1:3 in a micro-Kjeldahl flask.

Amount of metal present was 0.05–0.3 mg.

Urine was digested with concentrated  $\text{HNO}_3$  only.

(e.g., lithium metaborate, typically used at a 3:1 flux-sample ratio, introduces lithium and boron), loss of materials by volatilization, and the encouragement of sample contamination from the vessel walls, which also become solubilized. The properties of some useful fluxes are summarized in Table 3.

### Dissolution Techniques

Depending on the nature, origin, sample quantity, elements of interest, and concentration range, a variety of different techniques for sample dissolution can be used. Dissolution assemblies such as the Kjeldahl flask, Parr bomb, crucible, quartz and platinum vessels, PTFE containers, and specially designed apparatus can be used for wet digestion (Figures 1 and 2). Many suitable small vessels and devices for sample heating and filtering are available. In the case of classical milliliter, microliter, and nanoliter methods, solution concentrations are generally  $>0.01 \text{ mol l}^{-1}$ . The quantities of the decomposition reagents and the decomposition vessels are adjusted to the smaller sample weights.

Inorganic materials subjected for trace metal analysis are generally decomposed and solubilized by treatment with mineral acids or by fusion with fluxes. Some inorganic samples, e.g., soils, may also contain considerable amounts of organic material, which can also be solubilized by acid treatment. Faster and more efficient decompositions of both organic and inorganic materials is possible using closed reaction vessels (bombs) that allow higher temperatures and pressures to be applied. For example, bombs have been designed for the decomposition of silicates with

**Table 3** Common fluxes

Flux	Melting point ( $^{\circ}\text{C}$ )	Type of crucible/dish for fusion	Type of substance decomposed
$\text{Na}_2\text{CO}_3$	851	Pt	For silicates and silica containing samples; alumina-containing samples; sparingly soluble phosphates and sulfates
$\text{Na}_2\text{CO}_3$ + an oxidizing agent such as $\text{KNO}_3$ , $\text{KClO}_3$ , or $\text{Na}_2\text{O}_2$	318	Pt (not with $\text{Na}_2\text{O}_2$ ), Ni	For samples requiring an oxidizing environment; that is, samples containing S, As, Sb, Cr, etc.
$\text{NaOH}$ or $\text{KOH}$	380	Au, Ag, Ni	Powerful basic fluxes for silicates, silicon carbide, and certain minerals; main limitation: purity of reagents
$\text{Na}_2\text{O}_2$	Decomposes	Fe, Ni	Powerful basic oxidizing flux for sulphides; acid insoluble alloys of Fe, Ni, Cr, Mo, W and Li; platinum alloys, Cr, Sn, Zr minerals
$\text{K}_2\text{S}_2\text{O}_7$	300	Pt, porcelain	Acid flux for slightly soluble oxides and oxide-containing samples
$\text{B}_2\text{O}_3$	577	Pt	Acid flux for decomposition of silicates and oxides where alkali metals are to be determined
$\text{CaCO}_3 + \text{NH}_4\text{Cl}$		Ni	Upon heating the flux, a mixture of $\text{CaO}$ and $\text{CaCl}_2$ produced; used to decompose silicates for the determination of the alkali metals

hydrofluoric acid at temperatures up to 150°C and pressures in excess of 8000 kPa. In the milligram range, the Parr bomb using metallic sodium or the Wurzschnitt bomb using sodium peroxide can be used to decompose refractory substances.

## Contamination and Loss of Analyte

### Contamination

The introduction of foreign substances during wet digestion and sample processing may have serious consequences in elemental analysis, and sources of contamination and their likely impact should be anticipated in order to minimize the resulting errors.

Airborne contaminants, in the form of dust, corrosion products, and residues from paints, etc., can introduce many different elements into a sample, e.g., sodium, potassium, calcium, magnesium, and aluminum. This is a significant threat where open reaction vessels are used, and can be avoided by simple precautionary measures such as covering the dissolution vessel with a dish or beaker equipped with a side arm through which a stream of filtered air or gas is passed. More stringent measures include the use of a clean air room kept under positive pressure, with the reaction itself carried out under a laminar flow hood. Gaseous contaminants can be eliminated from the reaction vessel's air supply using appropriate adsorption filters.

Another significant source of contamination is the vessels used for reagent storage and decomposition. There is no such thing as a completely inert vessel, although the choice of an appropriate vessel that is the least reactive under the chosen storage or decomposition conditions is recommended. **Table 4** shows the elemental composition of four materials commonly used in decomposition and storage vessels, therefore revealing likely contaminants and the proportions in which they would be found. Dissolution vessels of Pyrex and quartz can introduce contamination from many elements, but ultrapure quartz can reduce the level of contamination from trace elements by up to 1000-fold as long as the surfaces are scrupulously cleaned before use. Polypropylene bottles, which are often used for the storage of acids, become brown after some time indicating the dissolution of the vessel's organic material. Even platinum vessels, which are required for fusions, contain small amounts of contaminating iron that can dissolve in contact with an acidic solution.

As well as the reaction and storage vessels, contamination may also arise from other stages of sample processing. Filter paper can contaminate samples with aluminum, barium, calcium, chromium, copper, iron, germanium, potassium, manganese, magnesium, sodium, antimony, gold, titanium, vanadium, zinc, zirconium, and rare earth metals. It is best to use filter media other than paper and carry out extensive preliminary washing with the operating solutions. Ultrapure water should be used as distilled water contains trace amounts of several

inorganic compounds, resulting in contamination with copper, zinc, iron, nickel, aluminum, lead, and others.

Contaminants originating in the mineral acids used for digestion are also a significant source of error. **Table 5** shows the contaminants present in reagent grade and extra-pure mineral acids available from standard laboratory suppliers. Extra-pure acids have low levels of contaminants but are very expensive. It may be possible to eliminate many of the trace contaminants from reagent grade acids, or at

least reduce them to undetectable levels, by several rounds of distillation.

### Losses

During wet digestion, certain components of the sample can be lost, leading to the underestimation of particular elemental contents. Trace elements can be lost by adsorption to the vessel walls, volatilization, coprecipitation, and coextraction. Although the exact nature of adsorption losses is unclear, it may

be due to molecular and ionic interactions. Metal cations exchange with alkali or alkaline earth ions at the glass-solution interface and are replaced by  $\text{H}^+$  ions. Anion exchange may also occur, e.g.,  $\text{AuCl}_4^-$  for  $\equiv\text{SiOH}$  groups on the glass surface. Vigorous shaking of the solution may bring some of the absorbed species back into solution. Polyethylene and polypropylene also adsorb inorganic and molecular species but to a lesser extent and a mature acid strength of 10% is recommended in stored solutions. Solutions of  $0.1 \text{ mol l}^{-1}$  or stronger in mineral acid stored in polyethylene, Pyrex, or similar borosilicate glass bottles remain stable for weeks. Plastic bottles may be preferred because of reduced leaching of trace elements. Sample solutions of water should be acidified to prevent or minimize the adsorption of metals. Mercury concentrations in  $1 \text{ mol l}^{-1}$  nitric acid in borosilicate glass do not show any loss over a period of months. Loss of analyte also occurs when filtered through paper, sintered glass, or glass wool due to adsorption. Centrifugation is therefore preferable to filtration.

Volatile metals are less likely to be lost from basic solutions than from acidic ones. Metals with higher oxidation states tend to form volatile oxides and halides, e.g.,  $\text{OsO}_4$ ,  $\text{RuO}_4$ ,  $\text{Re}_2\text{O}_7$ ,  $\text{GeCl}_4$ ,  $\text{AsCl}_3$ ,  $\text{SbCl}_3$ ,  $\text{CrOCl}_2$ ,  $\text{SnCl}_4$ , and  $\text{TiF}_4$ . A few metals can be lost from solutions by volatilization at room temperature, particularly  $\text{OsO}_4$  and  $\text{RuO}_4$ . Losses associated with the reaction of samples with silica glass, porcelain, and platinum at higher temperatures may also take place.

### Matrix Effects and Modifiers

Many samples with inorganic or organic matrices pose serious problems in elemental analysis due to their composition and nature. It may therefore be necessary to add certain modifiers to the mixture to facilitate dissolution. In addition, dissolution assemblies may need to be modified. The use of hydrogen peroxide, a nonacidic modifier, has already been described. This can be used in conjunction with suitable acids for effective oxidation, and decomposition of organic matter usually proceeds without the danger of an explosion in a mixture of nitric and sulfuric acids at atmospheric pressure. One common modification of dissolution assemblies is the fitting of a condenser, to prevent the loss of volatile mercury, osmium, and ruthenium species. If excessive frothing occurs during wet digestion, a small amount of 2-octanol may be added or the preliminary treatment may be carried out in a beaker with glass beads to prevent bumping. With some organic materials, e.g., rubbers, coated fibers, and polymers, wet digestion in

sulfuric acid should not be carried out if the aim is to determine levels of arsenic. The ammonium salt of ethylenediaminetetraacetic acid is often used as a matrix modifier for the dissolution of sediments and other geological samples with hydrofluoric, sulfuric, and perchloric acids.

Digestion with a mixture of nitric, sulfuric, and perchloric acids is more efficient when a small amount of molybdenum(IV) catalyst is added. As soon as water and nitric acid have evaporated, oxidation proceeds vigorously with foaming and is completed in a few seconds. To avoid the loss of mercury from a digestion, volatile mercury compounds can be reduced to the metal with copper(I) and hydroxylammonium chloride at room temperature, while organic matter is degraded by potassium permanganate. The mercury can then be dissolved and the analysis completed. Nitrogen-containing compounds are commonly digested with sulfuric acid and potassium sulfate to increase the boiling point of the acid and thus the efficiency of the reaction. Proteins can be removed from organic samples by precipitation using trichloroacetic acid, tungstic acid with barium hydroxide, or zinc sulfate.

For the decomposition of inorganic samples by soda ash in platinum crucibles, the resistance of platinum is increased in an atmosphere of carbon dioxide. In a nitrogen atmosphere, platinum is corroded less by alkali metals. Peroxide bombs are good for wet ashing to destroy the organic matter in samples like coal. The PTFE acid digestion bomb prevents contamination and insures no losses by volatilization. Samples like coal can be analyzed in quantities of 50 mg or less.

In the fusion methods, cesium iodide is often added to the fusion mixture as a nonwetting agent to prevent the molten flux from adhering to the walls of the vessel, as well as to prevent incomplete transfer of the bead to the acid solution. In wet digestion of coal and fly ash using the Parr bomb, boric acid is added after digestion and the sample is heated for a further time on a water bath allowing the removal of unburned carbon.

No method of wet digestion is ideal, and both contamination and losses will occur to a greater or lesser degree whichever method is used. The task of the analytical chemist is to choose a procedure that will minimize interference from contaminants, reduce losses as much as possible, and therefore bring errors within acceptable limits. At all times, blank reagents and spiked recovery experiments are required to establish the degree of analyte contamination and loss from the dissolution process.

## Introduction

The widespread use of microwaves for dissolution of samples is gradually replacing the conventional pressure reactors. This is particularly true in the determination of inorganic and organic analytes. Sample dissolution can be conducted in both closed and open systems.

A wet mineralization procedure using high pressure (and also high temperature), based on microwave decomposition with acid in hermetic Teflon containers, has recently been proposed. Sample heating is carried out in special microwave ovens that currently exist in the market. The speed of wet mineralization and the decomposition efficiency increase spectacularly when this type of equipment is used. For example, it has been observed that decompositions that require several hours at atmospheric pressure can be completed in a few minutes with the microwave technique. The other advantage is that it requires small quantities of the reactive substance, thus significantly reducing the magnitude of blanks.

Traditional methods of samples preparation do not give good reproducibility; however, the use of microwave irradiation rather than convection and/or conduction heating reduces errors in the sample preparation process. The method also addresses other parameters such as time required for analysis and sample contamination.

In 1975, microwaves were first used as rapid-heating sources for wet, open-vessel digestions. They were used to heat acids rapidly, in Erlenmeyer flasks, to digest biological matrices, and the conventional sample digestion times were reduced from 1–2 h to 5–15 min.

In the beginning, microwave sample preparation made use of common laboratory glassware and open Teflon vessels to digest matrices at the boiling point of the acids in commercial microwave ovens. In the 1980s, researchers began using specially designed

closed vessels for microwave digestions to achieve reaction temperatures above the atmospheric boiling points of the acids in order to increase the reaction rates and decrease reaction times.

## Theoretical Aspects

Microwaves are electromagnetic waves with frequencies in the range of 300–300 000 MHz. Microwave radiation neither possesses ionizing characteristics nor produces changes in the molecular structure; it can be used to measure the movement of molecules due to the migration of ions and the rotation of dipoles. Of the four frequencies most often used in industrial and scientific applications ( $915 \pm 25$ ,  $2450 \pm 13$ ,  $5800 \pm 75$ , and  $22\,125 \pm 125$  MHz), the one with a power range 600–700 W (domestic ovens) is 2450 MHz, which can provide, to the microwave cavity,  $\sim 43\,500$  cal in 5 min.

The warming of a sample through microwave action depends on the dissipation factor ( $\delta$ ), which is defined as the ratio of the dielectric loss factor of the sample ( $\epsilon''$ , which defines the efficiency of the dielectric medium to convert microwave energy into heat) and its dielectric constant ( $\epsilon'$ , a measure of the polarizability of the molecules in an electric field). Materials can reflect microwaves (e.g., metals), transmit them without being absorbed (e.g., transparent materials), or absorb them (e.g., dielectrics). All materials display these characteristics to varying degrees. The dissipation factor ( $\tau$ ) of the material is a good measure of its ability to heat up under microwaves: larger the dissipation factor, greater is the heat absorbed by the sample.

The dissipation of energy of the microwaves in a sample affects its transmission, which also depends on the frequency of the radiation (it is inversely proportional to the square root of the frequency).

Energy dissipation in a sample is caused by its warming and is basically produced by two mechanisms that generally operate simultaneously: ionic conduction and dipole rotation.

## Introduction

The widespread use of microwaves for dissolution of samples is gradually replacing the conventional pressure reactors. This is particularly true in the determination of inorganic and organic analytes. Sample dissolution can be conducted in both closed and open systems.

A wet mineralization procedure using high pressure (and also high temperature), based on microwave decomposition with acid in hermetic Teflon containers, has recently been proposed. Sample heating is carried out in special microwave ovens that currently exist in the market. The speed of wet mineralization and the decomposition efficiency increase spectacularly when this type of equipment is used. For example, it has been observed that decompositions that require several hours at atmospheric pressure can be completed in a few minutes with the microwave technique. The other advantage is that it requires small quantities of the reactive substance, thus significantly reducing the magnitude of blanks.

Traditional methods of samples preparation do not give good reproducibility; however, the use of microwave irradiation rather than convection and/or conduction heating reduces errors in the sample preparation process. The method also addresses other parameters such as time required for analysis and sample contamination.

In 1975, microwaves were first used as rapid-heating sources for wet, open-vessel digestions. They were used to heat acids rapidly, in Erlenmeyer flasks, to digest biological matrices, and the conventional sample digestion times were reduced from 1–2 h to 5–15 min.

In the beginning, microwave sample preparation made use of common laboratory glassware and open Teflon vessels to digest matrices at the boiling point of the acids in commercial microwave ovens. In the 1980s, researchers began using specially designed

closed vessels for microwave digestions to achieve reaction temperatures above the atmospheric boiling points of the acids in order to increase the reaction rates and decrease reaction times.

## Theoretical Aspects

Microwaves are electromagnetic waves with frequencies in the range of 300–300 000 MHz. Microwave radiation neither possesses ionizing characteristics nor produces changes in the molecular structure; it can be used to measure the movement of molecules due to the migration of ions and the rotation of dipoles. Of the four frequencies most often used in industrial and scientific applications ( $915 \pm 25$ ,  $2450 \pm 13$ ,  $5800 \pm 75$ , and  $22\,125 \pm 125$  MHz), the one with a power range 600–700 W (domestic ovens) is 2450 MHz, which can provide, to the microwave cavity,  $\sim 43\,500$  cal in 5 min.

The warming of a sample through microwave action depends on the dissipation factor ( $\delta$ ), which is defined as the ratio of the dielectric loss factor of the sample ( $\epsilon''$ , which defines the efficiency of the dielectric medium to convert microwave energy into heat) and its dielectric constant ( $\epsilon'$ , a measure of the polarizability of the molecules in an electric field). Materials can reflect microwaves (e.g., metals), transmit them without being absorbed (e.g., transparent materials), or absorb them (e.g., dielectrics). All materials display these characteristics to varying degrees. The dissipation factor ( $\tau$ ) of the material is a good measure of its ability to heat up under microwaves: larger the dissipation factor, greater is the heat absorbed by the sample.

The dissipation of energy of the microwaves in a sample affects its transmission, which also depends on the frequency of the radiation (it is inversely proportional to the square root of the frequency).

Energy dissipation in a sample is caused by its warming and is basically produced by two mechanisms that generally operate simultaneously: ionic conduction and dipole rotation.

**Figure 1** (A) Aligned polarized molecules in the electromagnetic field. (B) Thermally induced disorder when the electromagnetic field is removed. (Adapted with permission from Kingston HM and Jassie LB (1998) *Introduction to Microwave Sample Preparation, Theory and Practice*, ACS Professional Reference Book Series, p. 11, Washington DC: American Chemical Society.)

*Ionic conduction* refers to the migration of ions in the applied electromagnetic field. Assume that the energy dissipation, in the form of heat, corresponds to  $iR^2$ , due to the resistance to the ionic flow. The ionic conduction depends on the nature and mobility on ions and on their concentration in the dissolution. In this mechanism, the dissipation of microwave radiation increases with increasing temperature, which controls the digestion processes in the final warming stage of sample dissolution.

*Dipole rotation* is used for molecules that possess a permanent or induced dipolar moment in an electric field. Upon applying microwave radiation to a sample that contains dipolar molecules, the electromagnetic field induces the organization of the system, which, upon increasing the temperature, is disordered and returns to the initial state, and thus thermal energy is released (Figure 1).

When a radiation of frequency 2450 MHz is employed, the orientation of the molecules is changed  $4.9 \times 10^9$  times per second. The result of this alignment-disorder process is a rapid self-warming of the sample.

The efficiency of the dipole rotation mechanism, with respect to warming of the samples, depends on the characteristics of the sample molecules, especially the dielectric easing time, which in turn depends on the temperature and the viscosity of the sample. The contribution of the dipole rotation to the warming of the samples is quantified through the dielectric easing time ( $\tau$ ): the time required for the molecules of the sample to return to its disordered state (up to 63%). This implies that the maximum energy conversion occurs when the frequency of the microwaves coincides with the inverse of the easing time; when the sample presents a value of  $1/\tau$  close to the microwave frequency, high dissipation of energy is produced, which implies increased yield of the warming processes. On the contrary, if  $1/\tau$  is very different

**Figure 2** Heating in the microwave oven. Adapted with permission from Empleo de los Hornos de Microondas en Química, Valencia 1990.

from the microwave frequency, it produces a low dissipation of energy.

The value of  $1/\tau$  for water is greater than the corresponding value for the frequency of radiation (2450 MHz); it increases upon increasing the temperature: at temperatures of the order of 100°C, the ionic conduction prevails as compared to the dipolar rotation. Furthermore, for a given frequency, the warming of the samples is proportional to the applied power.

The customary procedure to establish the power of a microwave oven involves determining the temperature increase of a water pint (470 g) heated for 1 min; since  $\Delta E = cm\Delta T$ , where  $\Delta E$  is the absorbed energy,  $c$  the calorific capacity of water,  $m$  the water mass,  $\Delta T$  the temperature increase (in °F), so that  $P = \Delta T/18.2$ . Measuring  $\Delta T$  can be controlled by the power of the applied microwave radiation.

The clearly proportional (linear) behavior between warming and applied power is characteristic of very polar molecules; thus, for example, *n*-propanol behaves analogously to water, while carbon disulfide and carbon tetrachloride are practically not heated, and methyl palmitate presents a curve as a function of the time of exposure to the radiation that tends to be saturated, as can be seen in Figure 2.

From the above discussion, we can deduce that: as opposed to what occurs in a thermal stove, where the warming of the samples is produced by convection (transmission of thermal energy from the oven up to the walls of the container and from there to the molecules of the samples), in a microwave oven heat is generated by the polar molecules of the sample; the radiation results in an ordered state of the dipoles and is dissipated thermally in the sample itself, where heat is generated throughout, and there is no dissipation in the container on account of the slow convection processes that govern warming from an external source (Figure 3).

The practical conclusions of the processes induced in the dispersion of energy of the microwaves in an

**Figure 3** Comparison of heating in a thermal stove and a microwave oven. (Adapted with permission from Kingston HM and Jassie LB (1998) *Introduction to Microwave Sample Preparation, Theory and Practice*, ACS Professional Reference Book Series, pp. 16–17, Washington DC: American Chemical Society.)

oven are: very rapid warming and low energy consumption. Due to their rapidity and economy, the microwave systems can totally replace the traditional methods.

## Classification of Materials based on their Interaction with Microwaves

As mentioned earlier, materials are classified into three types, depending on their ability to absorb the microwave, allow the microwave to pass through, or reflect the microwaves.

Metals belong to the last group and therefore the use of metallic containers is not recommended. However, this characteristic is very important since it permits the design of a system of wave guides and protects users from radiation.

Transparent materials allow the microwaves to pass through without appreciable absorption. This property permits their use as insulating materials, as the heat loss of the samples is avoided and makes them particularly adapted for the construction of the vessels. Glass containers, ceramics, and some plastics are transparent. However, glass containers tend to be heated when they are exposed to high power for a long time.

Teflon is the most adequate material to build vessels: it is totally transparent to the microwave radiation, is resistant to all acids, has good thermal stability, and can sustain temperatures of up to 200°C, as opposed to polystyrene, which is only stable below 70°C. The only one application where it cannot be used is when concentrated phosphoric acid or sulfuric acid is used, since these acids have boiling points far above the fusion point of Teflon. In this case, quartz is the material that should be employed. Another material used often is polycarbonate, which resists the acids very well and has a fusion point of 135°C.

From the data for dissipation factors of different materials (at 3000 MHz, 25°C), it is deduced that compared to a value of  $\tan \delta = 157$  for water, quartz ( $\tan \delta = 0.06$ ) is the most transparent material. Teflon ( $\tan \delta = 0.15$ ), polyethylene ( $\tan \delta = 0.31$ ), polystyrene ( $\tan \delta = 0.33$ ), and some ceramics ( $\tan \delta \sim 0.55$ ) can be considered to be very transparent. Borosilicate glass ( $\tan \delta = 1.06$ ), phosphate glass ( $\tan \delta = 4.6$ ), Plexiglas ( $\tan \delta = 5.7$ ), poly(vinyl chloride) ( $\tan \delta = 5.5$ ), and nylon ( $\tan \delta = 12.8$ ) can also be considered as transparent, although they dissipate energy of the microwaves to a greater extent.

The materials comprising polar molecules, and especially liquids, absorb microwave radiation. Therefore, they can be heated easily in the ovens and hence are employed in reaction acceleration for dissolution and digestion of samples.

The different behaviors of the materials with respect to the microwaves must be taken into account during the manufacture of different components of the oven and for selection of vessels and acids for the dissolution of the samples.

## Components of Microwave Oven

### Magnetron

A magnetron generates microwaves (Figure 4). It comprises a cylindrical diode working as a cathode, an anode, and a magnet that generates a magnetic field aligned with the cathode. Between the cathode and the anode are found a series of coupled resonating cavities that ensure that when a power of a few thousands of volts is reached in the diode, the electrons are freed, resounded by the influence of the magnetic field, and oscillate the magnetron, thus initiating the emission of an antenna placed under a pipe in which vacuum is created. The magnetrons used in microwave ovens tend to have an exit frequency of 2450 MHz and provide an electromagnetic energy of 600 W for an electrical entry power of 1200 W.

### Microwave Guide

The radiation is focused on the microwave cavity through a wave guide. Waveguides are rectangular, metallic conductors that permit the reflection of radiation and guide it toward an objective. In a guide of dimensions  $a$  and  $b$  (Figure 4), when the ratio  $a/b$  is between 2 and 2.5, there is an electromagnetic wave of wavelength  $< 2a$  can propagate. Figure 4B indicates the relative direction of the electric and magnetic fields, which constitute the radiation, in the wave guide. This spread pattern is unique for waves with  $2a > \lambda > a$ ; more complex spread patterns exist for other radiations.

**Figure 4** (A) Microwave oven components. (B) Microwave guide. (Adapted with permission from Kingston HM and Jassie LB (1998) *Introduction to Microwave Sample Preparation, Theory and Practice*, ACS Professional Reference Book Series, pp. 18–19, Washington DC: American Chemical Society.)

In practice, the optimum radiation for a guide is one whose wavelength corresponds to a value of  $1.3a$  and, as a rule, a good yield is obtained for radiation for  $\lambda$  between  $1.1a$  and  $1.7a$ .

In domestic microwaves, the radiation of the magnetron is focused toward the cavity, which results in preferential heating locations in the sample.

In microwave ovens manufactured for sample analytical studies, two strategies have been used

(Figure 5): (1) one similar to that of the domestic ovens; and (2) where radiation is focused on the sample (which is the basis for microdigestion systems).

The function of microwave guides is to lead the radiation from the magnetron up to the cavity. However, when it has worked for long periods of time, at high power, and with a small quantity of absorbent material, a large part of radiation

**Figure 5** (A) Schematic microwave oven of type 1. (B) Schematic microwave oven of type 2. (Adapted with permission from Kingston HM and Jassie LB (1998) *Introduction to Microwave Sample Preparation, Theory and Practice*, ACS Professional Reference Book Series, p. 18, Washington DC: American Chemical Society.)

that arrives at the cavity is reflected and it can be at this point that the magnetron initiates its destruction.

To avoid the concentration of reflected radiation, the microwave ovens designed for the sample digestion tend to carry a terminal circulator that employs ferrites and static magnetic fields to guide the radiation reflected toward a chamber where it is dissipated.

### Microwave Cavity

A microwave cavity is where the containers and the samples are introduced. It is here that the warming and attack processes develop.

A cavity is in the form of rectangular base prism with a volume of 10–20 l, except in the systems of type 2, where smaller cavities are used, designed to couple the digestors in their interior.

The distribution of radiation in the cavity is always uniform, creating greater density points of irradiation. It has been proved, for some ovens, that the positions next to the fund are more irradiated than the zones nearer to the center and the door; therefore, revolving or stirring plates are employed at the exit of the wave guide, which permit averaging of the exposure of the samples to the irradiation. Modifying the conditions of the samples or altering the direction of the microwaves is done in a uniform manner.

The walls of the oven are metallic and facilitate the reflection of radiation and, when interfaced with an absorbent material, dissipation results, and the provoking sample heats up.

In laboratory work, and as a rule, when samples are digested with acids, precautions have to be taken to avoid the attack of the walls. They have been used in systems for smoke extraction, closed containers, and special protection of the walls with a polymeric recovering.

There are two types of adapted microwave ovens, especially for the work in laboratory:

1. Equipment of the type 1: maintain the basic structure of the kitchen ovens; incorporate a system

of evacuation of smokes and a circulator to avoid the reflected microwaves; use digestors with a meticulous control of pressure and temperature during the digestion.

2. Equipment of type 2: very different from the conventional ovens; the cavity is designed especially to house the reactors; the reactors receive all the power from the magnetron through the wave guide; work at atmospheric pressure; possible to program all the stages, from the addition of acids and reagents to time and work power.

### Applications

The higher efficiency of microwave ovens to permit the warming of the samples allows drying, favors the digestion with acid, and accelerates chemical reactions that are controlled by a slow thermal stage.

It can be deduced that the chemical systems where a microwave oven can provide important advantages have the following characteristics: polar nature of the samples or the 'middle of reaction', processes that require warming, and those where reaction products are not decomposed with the increase in temperature, which leads to their degradation due to the lack of a strict control of the reaction or digestion conditions.

The last point above does not affect components that can be separated in gaseous form at temperatures between 100°C and 200°C, since they could be retained in the reaction system using properly sealed systems as is the case of the recovery of Hg and As in samples digested with acid.

### Acid Digestion of Solid Samples in Microwave Ovens

It is best to attack the samples with an acid or a mixture of acids. Dielectric liquids, when heated in contact with dielectric particles, induce the warming

of the superficial molecules of the sample. This creates a convection current that agitates and destroys the superficial caps of the samples. The destruction of this cap exposes a new part of the sample, which is now attacked, and in this way the digestion of the sample progresses quickly.

The “warming and attack” of the sample is not produced by the effect of an external source of heat but is generated by interactions of the reaction mixture with the microwave radiation.

The mixture of the acids and the samples acts as an excellent absorbent of radiation. Kingston and Jassie accomplished a systematic study of the behavior of the mineral acids, employing the type-1 system and closed digestors provided with pressure and temperature sensors. The data from this work are very interesting for studying the digestion conditions of numerous types of samples and they can be a guide to finding the best acid or mixture for use.

Normally, it is desirable that the acid form soluble salts with the metallic ion of interest, and because of this  $\text{HNO}_3$ ,  $\text{HCl}$ , and their mixtures are the most used acids.

### **$\text{HNO}_3$**

It is used essentially due to its characteristic as a strong oxidant acid and the fact that nitrates are very soluble salts, useful for the subsequent dissolution of the residues. It has a low boiling temperature ( $120^\circ\text{C}$ ), which limits its employment in open thermal systems. In closed vessels, it behaves ideally:

- 5 ml to 144 W:  $176^\circ\text{C}$  and 5 atm in 8 min (vessel of 100 ml); and
- 3 ml to 258 W:  $175^\circ\text{C}$  and 4.5 atm in 2.5 min.

This temperature ( $175^\circ\text{C}$ ),  $\sim 50^\circ\text{C}$  more than the boiling temperature, increases its oxidative power and favors the digestion of the samples.

### **$\text{HCl}$**

It is a strong acid and, although not an oxidant, has a great complexing power; therefore, it is very useful in the digestion of metals, giving easily soluble chlorides (7.3 g to 430 W:  $175^\circ\text{C}$  and 7 atm in 2 min). In these conditions  $\text{Cl}_2$  is produced, which increased the oxidant power of the acid.

These high pressures, which are used to attack with  $\text{HCl}$ , can be a drawback for use in closed containers; therefore, they should be used extremely cautiously to avoid losses or breaking of digestors.

### **Mixtures of $\text{HCl}$ and $\text{HNO}_3$**

Aqua regia is the most known and used mixture, and is a good oxidant due to the formation of nitrosyl chloride ( $\text{NOCl}$ ). Upon heating, dissociation of  $\text{NOCl}$  into  $\text{Cl}_2$  occurs, which continues attacking the samples and produces an effective digestion in closed containers. This effect is the cause of the oxidation of many materials, which occurs more effectively than with  $\text{HNO}_3$  or  $\text{HCl}$  alone (8 ml to 316 W:  $180^\circ\text{C}$  and 7 atm in 16 min).

Use of  $\text{HF}$ ,  $\text{H}_2\text{SO}_4$ ,  $\text{H}_3\text{PO}_4$ , and  $\text{HClO}_4$  has also been described and their use is less recommended.

### **$\text{HF}$**

$\text{HF}$  attacks the skin, and its steam can damage vision; therefore, one must be extremely cautious in its use. The use of gloves, plastic syringes, and Teflon containers, as well as safety eyewear and an extraction chamber with good shot is recommended.

### **$\text{H}_3\text{PO}_4$ and $\text{H}_2\text{SO}_4$**

These acids have high boiling points that can fuse the Teflon.

### **$\text{HClO}_4$**

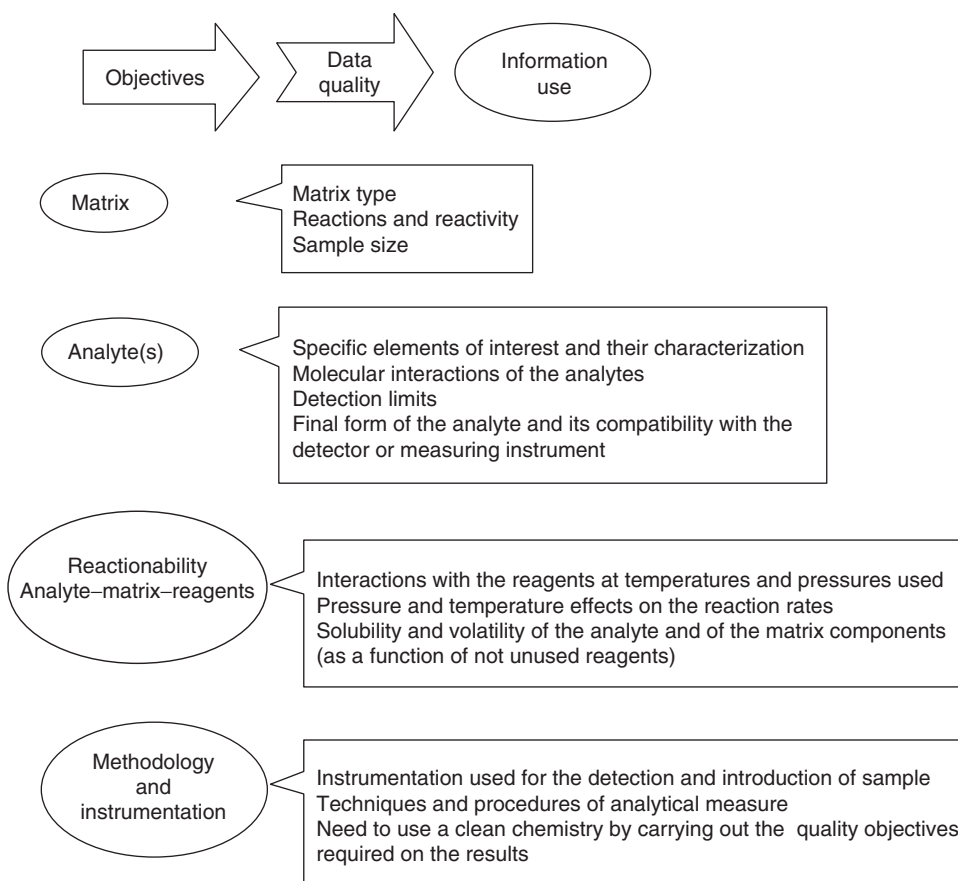

In the presence of organic samples,  $\text{HClO}_4$  could produce explosions.

## **Selection of a Microwave Sample Dilution Method**

Figure 6 gives a summary of factors that should be considered when selecting a microwave digestion method.

Acceptable errors in the results of analysis depend on the quality of data and so should in turn limit the acceptable errors of the process sampling, the blanks, etc. Often, for the same sample, not all the analytes possess the same priority and thus they do not require the same accuracy of the results.

The type of decomposition of the sample (reactive to use) depends on the nature of the matrix in reactors. Many matrices require  $\text{HF}$  to break the  $\text{Si-O}$  bonds of the silicates and  $\text{HNO}_3$  to oxidize the C. Organic samples (biological, botanical, polymeric pharmaceutical, etc.) and geological samples (soils, sediments, rocks, clays, etc.) are of interest for this type of treatment, since the C and the Si are transformed, by the acids mentioned, to volatile compounds ( $\text{CO}_2$  and  $\text{SiF}_4$ , respectively) and the

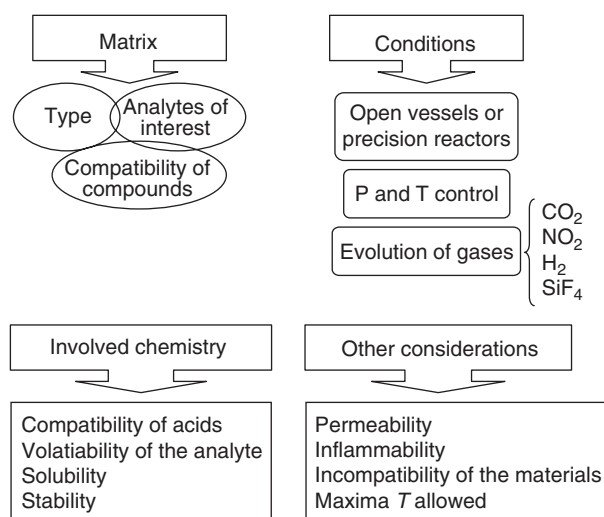

**Figure 6** Consideration of a selected method by microwave digestion. (Adapted with permission from Síntesis SA, *Toma y tratamiento de muestras*.)

transformation efficiency depends on the reaction temperatures.

With respect to the analyte, it must be taken into account that the matrix is soluble and stable in the digestion method selected. The concentration of the analyte in the sample should also be considered, since lesser the concentration greater is the need to obtain low quantification limits. The limits of detection and elemental interferences of the matrix can depend on the matrix-analyte-acid combination. The analysis technique should take extreme care to avoid interferences in the final detection. Thus, when inductively coupled plasma mass spectrometry is employed, the use of  $\text{H}_2\text{SO}_4$  and  $\text{HCl}$  can cause important spectral interferences that can completely annul the results.

Techniques that require the introduction of samples by nebulization, where physical interferences are avoided, for example, by variation of the viscosity of the sample are also interesting. On many occasions, to obtain a compatible dissolution, a subsequent treatment to the microwave digestion is required.

**Figure 7** Special considerations for the microwave oven sample preparation. (Adapted with permission from Síntesis SA, *Toma y tratamiento de muestras*.)

In summary, when microwave energy is employed in the sample digestion processes, the factors mentioned in **Figure 7** should be taken into account.

## Microwave Digestion of Various Sample Matrices

Methods based on microwaves have provided important improvements over the classical methods in terms of precision and efficiency.

### Organic Matrices

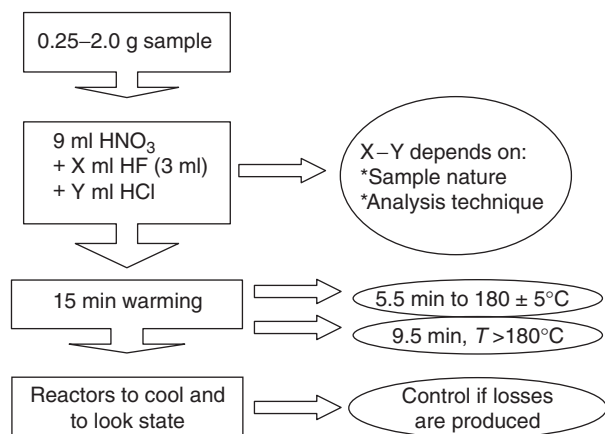

The decomposition of organic matrices in reactors to pressure by microwave is controlled temperature, that is, by adjusting the oxidation potential of  $\text{HNO}_3$ . The difficulty of mineralization of biological tissues depends on their composition.

In the case of botanical matrices, the addition of small quantities of HF is recommended to decompose the silicates present in small concentrations. The oxidation potential of  $\text{HNO}_3$  at  $180^\circ\text{C}$  is not sufficient for the decomposition of aromatic structures,

since these compounds or their degradation products cannot always be decomposed with  $\text{HNO}_3$  at temperatures  $\sim 300^\circ\text{C}$ . An incomplete decomposition of organic matter can give rise to serious interferences; for example, if electrochemical detection techniques are employed.

When biological samples are decomposed in open microwave systems, the use of  $\text{H}_2\text{SO}_4$  or  $\text{H}_2\text{SO}_4\text{--H}_2\text{O}_2$  is recommended; in the latter case, after burning of the organic matter by the addition of  $\text{H}_2\text{SO}_4$ , oxidation takes place completely due to  $\text{H}_2\text{O}_2$ , with the formation of  $\text{H}_2\text{SO}_5$ , which is decomposed at temperatures lower than the boiling point of  $\text{H}_2\text{SO}_4$ .

The dissolution of polymeric matrices is generally similar to that of other organic matrices ( $\text{HNO}_3$  is used, or in open systems  $\text{H}_2\text{SO}_4$  is added as an oxidizing agent). It must be taken into account that the hydrophobic nature of these samples causes a float on the surface of the reactors, which requires longer time for dissolution.

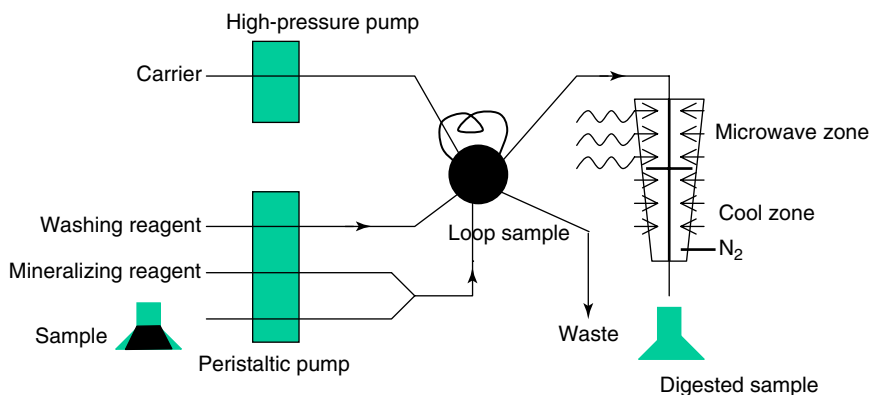

**Figure 8** Microwave assisted acid digestion of sediments, sludges, soils, and oils. (Adapted with permission from Síntesis SA, *Toma y tratamiento de muestras*.)

### Inorganic Matrices

Geological and metallurgical samples require very specific conditions for dissolution. Thus, if they contain silicates, HF should always be employed. A very general case of treatment would be the EPA-3052 method (Figure 8). This treatment results in appropriate dissolution of soils, rocks, sediments, etc.

### Environmental Matrices

One of the classic methods is 3051 developed by the EPA, and recently modified as method 3052. It is one of the most versatile methods and can be modified appropriately, depending on the characteristics of the matrices.

**Figure 9** Online schematic diagram of microwave digestion. (Adapted with permission from Síntesis SA, *Toma y tratamiento de muestras*.)

## Special Characteristics of Microwave Digestions for the Determination of Trace Analytes

The digestion methods in closed containers in reactors heated by microwaves provide an important reduction of the error risks introduced in the analysis when the samples are dissolved by traditional dry processes. One of the factors that contributes much to such reduction is the control of the blanks due to the following factors: the digestion takes place in

closed containers and pollution risks are reduced to a great extent; reagents of high degree of purity are used; the material of the reactors is very controlled and devoid of impurities; the time during which the sample is in touch with the reactor is very less compared to that in the classical methods; and risks are eliminated or reduced by the evaporation of volatile compounds.

Sample preparation using microwaves allows most reproducibility for treatment at ultratrace levels, in a given laboratory and between laboratories.

## Safety of Microwave Digestion Processes

Digestion by microwaves is more secure than other types of treatments as long as it takes into account a series of factors such as avoiding the use of explosive mixtures.

The most important aspects that should be considered are: type and size of sample, types of acids, relationship of sample/solvent, primary and secondary chemical reactions, content or production of inflammable products, microwave power, ramp and time, instrument and conditions of the reactors, and interactions of the microwaves.

## Trends of Microwave Employment

In spite of the fact that the microwave instrumentation of pressure reactors is relatively recent, it is used

in numerous laboratories and at present its applications are impressive.

It can be said that microwaves constitute the standard treatment method for the analysis of ultratracés together with technical detection such as inductively coupled plasma–atomic emission spectrometry and inductively coupled plasma–mass spectrometry.

## Online Processes

The automation of systems for sample preparation is still far from being implemented in laboratories for routine analysis. Up until now, automation has been done only for preliminary chemistry when only relatively simple processes are required, such as filtration, dissolution in water, extraction systems. The methods of flow injection analysis have contributed to the automation processes.

Automation in the quantitative mineralization of complex samples is very difficult; furthermore, systems that require digestion in pressure reactors are practically impossible to automate. Automation has not been introduced in sample analyses that need complex treatments.

The employment of microwave open digestors is the easiest route to carry out online digestion processes by the wet route.

Different designs have been introduced, in both continuous flow and stop flow, which are being applied for the automation of the process.

Figure 9 shows a plan of the last proposed designs: with the aid of peristaltic pumps, the sample and the digestion reactive is impelled to the microwave unit. The digestion region is formed by a Teflon pipe that passes through the warming and cooling zones of the microwave oven.

There exist numerous bibliographic references that reveal the current interest in the development of on-line methods of sample treatment.

## General Information for the Treatment of Different Types of Samples

As microwave sample preparation has evolved, standard microwave procedures have been developed and approved by numerous standard methods organizations. Table 1 summarizes the different methods approved for either microwave drying or microwave acid dissolution by the Association of Official Analytical Chemistry (AOAC), American Society for Testing and Materials (ASTM), the United States Environmental Protection Agency (US-EPA), Standard Method, and French and Chinese national methods.

## Introduction

The analytical steps of sample preparation have varying significance relative to their effect on the

precision and accuracy of the results of the analysis. Comminution of sample materials is one of the most essential, yet the most error-prone steps in the course of all chemical laboratory analysis tasks. Comminution usually refers to the conversion of solid samples with large particles mostly into powdery constituent substances of smaller particle size. The term is also infrequently used in conjunction with operations designed to convert liquids into droplets or gases into bubbles, the details of which will not be discussed further.

The aggregate state of the material to be homogenized does not undergo any change during these processes, whereas the physical and chemical characteristics of the sample may well change.

When comminuting crystalline substances, triboluminescence – a special form of luminescence – may be observed, so that the process can be made evident by way of adding triboluminescent substances.

The reasons for homogenizing sample material prior to performing the actual chemical/physical analysis are based on a great variety of requirements. The idea is usually to obtain a representative, i.e., evenly powdered sample for subsequent chemical/physical analysis. One of the problems encountered in sampling, especially in the field of ecological analysis, is the huge parent mass – anything between kilograms and tons – in the form of integral parts of a refuse dump, rock, debris of a specific stratum, etc. From this, a sample of only a few hundred milligrams may go into the measuring equipment for the actual analyses. In other words, the original sample is subjected to considerable decrease in bulk on its way to representing a proper analytical sample. It is important, however, to ensure that the make-up of this analytical sample represents the average chemical composition of the original sample.

Another major problem frequently encountered, specifically in the trace and ultratrace domains of ecological analysis, is the risk of contamination and/or volatilization of individual components. The risk of contamination is always present if the grinding elements themselves contain a high percentage of the substance to be determined (for example, iron and chromium in steel mills), or when certain readily volatilized combinations escape from the sample as a result of overheating.

The comminution process to be used normally depends on the following parameters:

- Total quantity and number of samples of the material to be homogenized.
- Initial particle size of the original sample.

- Ultimate fineness of the sample after comminution.
- Chemical/physical properties of the original sample and of the grinding elements (contamination/volatization).
- Hardness of the material to be homogenized.

There are three general comminution regimes:

- Coarse: grinding down to a particle size of  $\sim 5$  mm.
- Fine: grinding down to a particle size of  $63\ \mu\text{m}$ .
- Ultrafine: grinding down to a particle size of  $< 63\ \mu\text{m}$ .

## Theoretical Aspects

The basic operation of dividing solids into fractions by application of mechanical forces results in an increase of surface area, the magnitude of which depends primarily on the particle size, as is demonstrated in Table 1.

The term particle (or grain) size refers to the structural make-up of such substances as granulates, powders, dusts, granular mixes, and suspensions. Knowledge of the particle size, in conjunction with the comminution process, determines such details as grinding efficiency and ultimate product fineness. To establish particle sizes and their distribution within powdered systems, the user can have recourse to a number of different measuring processes designed to indicate, with appropriate particle definition, details of the probable equivalent diameter of a particle.

It follows that individual measuring methods depend upon particle definition. Particle definitions might include such details as number, length, surface area, mass, and volume, as a result of which one has the choice of using various counting methods – microscopy, image analyzers, laser diffraction, as well as sieving and air classification methods.

The details of a particle-size analysis are presented in tabular and diagrammatic form covering quantitative

**Table 1** Total increase of surface area upon disintegration of a cube of  $1\text{ cm}^3$  initial volume

Edge length	Number of cubes	Total surface area
1 cm	1	$6\text{ cm}^2$
1 mm	$10^3$	$60\text{ cm}^2$
0.1 mm	$10^6$	$600\text{ cm}^2$
0.01 mm	$10^9$	$6000\text{ cm}^2$
$1\ \mu\text{m}$	$10^{12}$	$6\text{ m}^2$
$0.1\ \mu\text{m}$	$10^{15}$	$60\text{ m}^2$
$0.01\ \mu\text{m}$	$10^{18}$	$600\text{ m}^2$
1 nm	$10^{21}$	$6000\text{ m}^2$

mass fractions, and cumulative and/or frequency density as a function of the equivalent diameter.

The following classification into millimeter ranges can be applied as a quantitative definition of particle/grain sizes:

Giganto grained > 300 mm  
 Giant grained 30–300 mm  
 Large grained 10–30 mm  
 Coarse grained 3–10 mm  
 Medium grained 1–3 mm  
 Small grained 0.3–1 mm  
 Fine grained 0.1–0.3 mm  
 Dense grained 0.03–0.1 mm  
 Microcrystalline 1–30  $\mu\text{m}$   
 Cryptocrystalline 0.1–1  $\mu\text{m}$   
 X-ray crystalline < 0.1  $\mu\text{m}$

An important factor governing the efficiency of any comminution process is the fracturing behavior of a sample. **Figure 1** demonstrates varying behaviors upon application of different stress-strain mechanisms:

1. *Fracturing behavior between two surfaces (Figure 1A).* The sample is wedged between two solid surfaces, which could be the surfaces of grinding assembly components or those of adjacent particles, and exposed to pressure load. Comminution here is, in particular, the result of pressure and frictional forces.

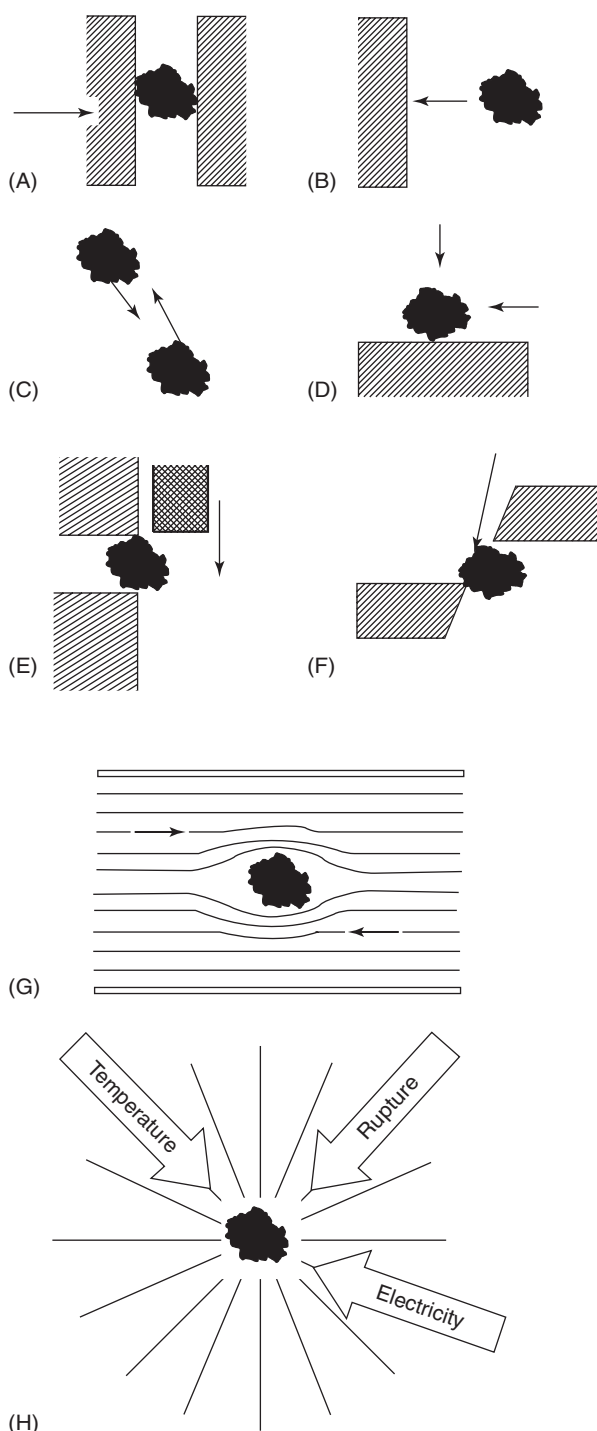

2. *Fracturing behavior upon contact with a single surface (Figures 1B and 1C).* The pressure effect here is produced upon contact with a single surface, which could be the solid surface of a grinding assembly component or of another particle within the sample.

3. *Fracturing behavior upon exposure to pressure and friction (Figure 1D).* Here the loading effect between two solid surfaces is in the form of a vertical force in combination with a horizontal, centric, or eccentric rotation, to bring about comminution.

4. *Fracturing behavior upon exposure to a shearing force (Figure 1E).* The loading effect is produced between two solid surfaces in the form of a shearing effect, i.e., comminution is brought about by way of impact and/or rebound effects generated between two counteracting surfaces or one moving and one static surface.

5. *Fracturing behavior upon exposure to a cutting effect (Figure 1F).* The loading effect is produced by two sharp-edged surfaces with their edges counteracting diametrically.

6. *Fracturing behavior upon exposure to the ambient medium (Figure 1G).* A loading effect due to the

**Figure 1** Fracturing behavior of sample constituents upon application of different stress-strain mechanisms. For details see text. (Modified from Pitsch H (1993) *Comminution*. Retsch Company, Rheinische Strasse 36, PO Box 1554, Haan W-5657, Germany; with permission.)

ambient or surrounding medium at a high shearing gradient can only be accomplished with low-strength materials, e.g., agglomerations or those with low degrees of hardness.

7. *Fracturing behavior upon exposure to nonmechanical energy* (**Figure 1H**). This loading effect on solid particles is caused by application of thermal loads without additional mechanical energy, i.e., by overheating, embrittling, or electric discharge.

Another important criterion for the quality of a comminution process is the subsequent homogeneity of the sample material, i.e., the distribution of the substance to be analyzed within the sample. A high degree of homogeneity may be obtained by blending the sample material, after comminution, in a suitable machine. This method counteracts the segregation tendencies of the sample material that result from variations in the distribution of particle sizes and is of particular importance whenever homogenized samples are bottled to serve as, for example, reference material (i.e., substances with a defined chemical composition) for quality control in chemical analysis. It must be ensured that each bottle of the total charge has exactly the same content ('between-bottle homogeneity') and that the contents of the single bottles represent the same average chemical composition ('within-bottle homogeneity'). To this end the material is analyzed for the component, with an appropriate number of repeat analyses. Once it has been established that the standard deviation is within tolerable limits, the sample material can be looked upon as being homogeneous. **Figure 2** shows an example of cadmium determination in white cabbage for the preparation of reference material for vegetable matrices.

## Contamination

Every comminution process involving solid surfaces in combination with kinetic energy input is likely to

**Figure 2** Quantitative determination of cadmium by solid sampling atomic spectrometry in a new candidate reference material (BCR-white cabbage; intake: 0.2–5 mg per measurement). Horizontal lines indicate tolerance limits. (From Markert, 1996.)

be accompanied by corresponding abrasion of the grinding assembly components. The resulting abrasive effect tends to increase grinding tool wear and to decrease tool life and grinding efficiency. More critically, the abrasion fines contaminate the sample stock during the grinding process. To minimize this risk of contamination, it is recommended practice to ensure that the abrasion resistance of the grinding assembly components is always higher than the hardness of the sample stock.

Hardness refers to the resistance offered by a solid body, i.e., the sample (glass, ceramics, minerals, etc.), when exposed to mechanical stress loads. High hardness ratings are typical for minerals, some of which are therefore well suited for use in lubricants and grinding and polishing compounds. Friedrich Mohs, an Austrian mineralogist, compiled an empirical scale of scratch hardness ratings in 1812 that is still applicable and is used to determine the hardness of minerals (see **Table 2**). Mohs hardness ratings are established by using the next higher mineral on the Mohs Hardness Scale to scratch-test a lower mineral on the scale: e.g., quartz (7) leaves a scratch on feldspar (6) but not on topaz (8).

The risk of contamination by individual process abrasives is particularly high in trace and ultratrace element analysis and is, therefore, primarily responsible for falsification of analytical results. Remembering that abrasion fines originating from grinding assembly components are always likely to contaminate sample material, the risk is best avoided by making sure that the component to be analyzed is not present in the grinding tools. The major components of individual grinding elements are listed in **Table 3**; the values necessarily represent only approximations and values are likely to vary with source and/or manufacturing process. Plastic material has recently been introduced for use in comminution equipment. The German government has launched an ecological sample base project in the course of which a mill with polytetrafluoroethylene rods (to serve as grinding elements) was conceived which produced

noncontaminated homogenized ecological samples under liquid-nitrogen conditions.

## Methods of Sample Processing

Grinding equipment used for comminution operations in chemical analysis varies in design and layout with application requirements, i.e., sample make-up, desired degree of particle size decrease, etc. The selection of the grinding kit to be used depends on

the problem and the requirements with respect to the desired sample fineness and freedom from contamination. In view of the extremely wide range of grinding kits available on the market, it is best to concentrate on their major objectives.

In general, the complexity of the enormous variety of comminution problems and requirements rules out any hope for a single, ideal comminution process. It happens quite frequently that processing of one sample involves the combined use of different grinding processes; for example, coarse grinding followed by fine grinding.

Given the multitude of existing comminution processes, we shall discuss two coarse, two fine, and three ultrafine grinding methods.

### Coarse Grinding (Down to 5 mm Particle Size)

There are many cases where the initial particle size of the sample requires preliminary reduction. Classical machines for this purpose are jaw crushers, normally used with samples of medium to extreme hardness as well as brittle to hard-tenacious samples, and cutting mills, used with samples of soft and tough make-up.

**Jaw crushers** These are used to break up substances with medium to extreme hardness ratings as well as brittle to tough materials, such as bakelite, bauxite, concrete, dolomite, ores, feldspar, ferroalloys, granite, glass, limestone, gravel, coal, coke, corundum, synthetic resins, quartz, salts, slag, silicates, sintered products, and many other substances.

Jaw crushers are normally upright floor models used for preliminary purposes in laboratories and at production plant level. They are designed for continuous operation and are therefore suitable for inclusion in fully automated and semiautomatic processing systems in production plants and laboratories. The efficiency and performance data (throughput rate, feed particle sizes, and ultimate fineness) of jaw crushers depend upon the disintegrating behavior and hardness rating of the material to be handled and on the size of the machine. **Figure 3A** shows that the grinding chamber is funnel shaped and tapers toward the adjustable outlet gap. These crushers incorporate a static and an eccentrically driven crushing jaw between which the breaking process takes place. The ellipsoidal movement of the driven crushing jaw provides for a continuous material flow toward the crusher outlet, from where it passes into a receptacle once broken down to the desired size.

**Cutting mills** These are designed to disintegrate bulky, soft, medium-hard, as well as fibrous and

**Figure 3** Operating principles of different comminution processes. See text for details. (Modified from Pitsch H (1993) Comminution. Retsch Company, Rheinische Strasse 36, PO Box 1554, Haan W-5657, Germany; with permission.)

cellulosic materials, and are used in agricultural research institutes and the plastics and pulp industries. Cutting mills are suitable for use with foliage, fibers, floor covering material, feedstuff, spices and herbs, rubber, grasses, hay, hops, wood, cardboard, plastics, leather, malt, Indian corn, paper, straw, tobacco, peat, paste products, roots, and twigs. **Figure 3B** shows that comminution of the material is brought about by a combined cutting and shearing effect. The material remains in the grinding chamber for no longer than is required to reach the desired fineness. The inlet zone is provided with a wooden tamper to facilitate handling of bulky or extremely light material. The attainable ultimate fineness depends on the size of interchangeable sieves located in the discharge zone.

#### Fine Grinding (Particle Size 5 mm to 63 $\mu\text{m}$ )

**Vibratory disk mills** These are designed for rapid, efficient, and lossless fine-grinding of medium-hard, hard-brittle, as well as tough materials in dry and wet conditions. They are specifically suitable for use with such substances as soil samples, ores, coal, coke, corundum, metal oxides, minerals, dry plant samples, slag, silicates, cement, cement clinker. **Figure 3C** shows that the sample material is ground down by

combined impact and friction effect generated between the grinding media and the jar wall surface. The grinding jar is fitted with the grinding tools (disk and/or rings) and loaded with the sample, after which the jar is closed and locked in the clamping fixture. When the machine is switched on, the mounting pad begins to oscillate, generating high dynamic mass forces during the grinding process.

**Mortar mills** These are designed for work with soft, hard, and brittle materials with hardness ratings of up to 8.5 Mohs. Mortar mills are particularly suitable for wet or dry grinding and homogenizing of such substances as ashes, chemicals, drugs, enamels, bauxite, dolomite, limestone, dry clay, kaoline, ores, coloring substances, rocks and debris, glass, synthetic resins, pharmaceutical products, salts, sand, chamotte, fireclay, slags, silicates, cement clinker, and similar materials. The ultimate fineness of samples produced in mortar mills depends on both the grinding time and the fracturing behavior of the substance to be handled. **Figure 3D** shows that the sample is loaded into the mortar located on a mounting pad. When the cover is closed and the machine switched on, the pestle follows the rotational movement of the mortar body, thus grinding the sample between the lower edge of the pestle and the rounded mortar wall.

#### Ultrafine Grinding (Particle Sizes <63 $\mu\text{m}$ )
